## ABSTRACT

We consider the controllability problem for finite-dimensional linear autonomous control systems, under state constraints but without imposing any control constraint. It is well known that, under the classical Kalman condition, in the absence of constraints on the state and the control, one can drive the system from any initial state to any final one in an arbitrarily small time. Furthermore, it is also well known that there is a positive minimal time in the presence of compact control constraints. We prove that, surprisingly, a positive minimal time may be required as well under state constraints, even if one does not impose any restriction on the control. This may even occur when the state constraints are unilateral, like the nonnegativity of some components of the state, for instance. Using the Brunovsky normal forms of controllable systems, we analyze this phenomenon in detail, that we illustrate by several examples. We discuss some extensions to nonlinear control systems and formulate some challenging open problems.

## 1. Introduction

Let  $n \in \mathbb{N}^*$  and  $m \in \mathbb{N}^*$  be integers, with  $m < n$ . Let  $A$  be an  $n \times n$  matrix and  $B$  be an  $n \times m$  matrix, with real coefficients, satisfying the Kalman condition

$$\text{rank}(B, AB, \dots, A^{n-1}B) = n. \quad (1)$$

Throughout the paper, we consider the linear autonomous control system

$$\dot{y}(t) = Ay(t) + Bu(t) \quad (2a)$$

with some initial condition

$$y(0) = y^0 \quad (2b)$$

where  $y(t) \in \mathbb{R}^n$  is the state and  $u(t) \in \mathbb{R}^m$  is the control. In order to avoid confusion, we will sometimes write  $y(t; u)$  the solution of (2). It is well known that, given any two points  $y^0$  and  $y^1$  of  $\mathbb{R}^n$  and given any time  $T > 0$ , there exists a control  $u \in L^\infty((0, T), \mathbb{R}^m)$  such that the corresponding trajectory, solution of (2), satisfies  $y(T) = y^1$ . In other words, one can pass from any initial condition to any final one *in arbitrarily small time*. Of course, this is at the price of using controls that have a  $L^\infty$ -norm that is larger as the transfer time  $T$  is smaller (Seidman & Yong, 1996). Therefore, under the Kalman condition (1), if there is no state and control constraint in the control problem, then the *minimal controllability time*, defined as the infimum of times required to pass from  $y^0$  to  $y^1$ , is equal to 0.

Now, we consider a connected subset  $C \subset \mathbb{R}^n$  with nonempty interior, standing for state constraints that we want to impose to

the controllability problem, and we address the following question:

*Given any two points  $y^0$  and  $y^1$  in  $C$ , is it possible to steer the control system (2) from  $y^0$  to  $y^1$  in arbitrarily small time  $T$ , while guaranteeing that  $y(t) \in C$  for every  $t \in [0, T]$ , or is there a positive minimal time required?*

We stress that we impose *no control constraint*, i.e.,  $u(t) \in \mathbb{R}^m$ , but we impose a state constraint. It is surprising that this apparently simple question has not been investigated before. It is the main objective of this paper to explore it.

Before going further, it is useful to note that controllability under control constraints but without state constraints is well understood (see Brammer, 1972) and can be studied by usual optimal control methods (see Lee & Markus, 1967; Trélat, 2005). Recall that, when there is a control constraint  $u(t) \in \Omega$  with  $\Omega$  a compact subset of  $\mathbb{R}^m$  then the set  $\text{Acc}_{\Omega}(y^0, T)$  of accessible points from  $y^0$  in time  $T > 0$  with controls  $u \in L^\infty((0, T), \Omega)$  is compact and convex and evolves continuously with respect to  $T$ : hence in this case the minimal time required to pass from  $y^0$  to  $y^1 \neq y^0$  is always positive.

Here, in contrast, we want to investigate the question of knowing whether the minimal time may be positive when imposing state constraints but no control constraint. Of course, in order to address this question we may first wonder whether the target point  $y^1$  is reachable or not from the initial point  $y^0$ . This is the question of controllability under state constraints, which is not the objective of the present paper but on which we shortly comment hereafter.

**Controllability under state constraints.** When  $C$  is a proper subset of  $\mathbb{R}^n$ , the question of controllability under the state constraint  $y(\cdot) \in C$  is complicated. Even under the Kalman condition, very simple state constraints can immediately make fail the controllability property. For instance, take the control system in  $\mathbb{R}^2$

$$\dot{y}_1(t) = y_2(t), \quad \dot{y}_2(t) = u(t),$$

and the state constraint  $y_2(t) \geq 0$  on the second component of the state. For any trajectory, the first component  $y_1(t)$  must be nondecreasing, and then obviously one cannot pass from any point to any other.

Controllability under state constraints has not been much investigated in the literature, certainly due to the difficulty of the question, even for linear control systems. Early conditions were given in Krastanov and Veliov (1992), with the idea of deriving conic directions of expansion of the reachable set. A more achieved version appears in Krastanov (2008), where the author states a necessary and sufficient condition for small-time controllability of linear control systems under conic state constraints. The verification of such algebraic conditions (given in terms of convex hull) remain however quite technical. In Heemels and Camlibel (2007), controllability is established under appropriate invertibility conditions of the transfer matrix and adequate Hautus test conditions. We also mention the recent paper (Le & Marigonda, 2017) for sufficient controllability conditions for nonlinear control systems.

In this paper, our objective is, when we already know that  $y^1$  can be reached from  $y^0$  under state constraints, to investigate whether the minimal time may be positive or not, while keeping the connecting trajectory in the set  $C$ .

It is anyway interesting to note that there is a specific situation under which controllability under state constraints can easily be proved, within a transfer time that may however be quite large. This is when  $y^0$  and  $y^1$  are *steady-states* (a point  $\bar{y} \in C$  is a *steady-state* if there exists  $\bar{u} \in \mathbb{R}^m$  such that  $A\bar{y} + B\bar{u} = 0$ ). This situation is studied in Section 4.1. More precisely, we prove in this section that, under a slight condition on the set  $C$  (which is satisfied if  $C$  is convex), it is possible to steer the control system (2) from any

steady-state  $y^0 \in \hat{C}$  to any steady-state  $y^1 \in \hat{C}$  in time sufficiently large, while ensuring that the corresponding trajectory remains in the interior  $\hat{C}$  of the set  $C$ . The proof is done by an iterative use of a local controllability result along a path of steady-states (whence the possibly large transfer time). The question is then to know whether one could find a control for which this transfer time would be arbitrarily small.

**Minimal controllability time.** We investigate the minimal time problem for the system (2) under state constraints  $y(\cdot) \in C$ , without control constraint. Given  $y^0, y^1 \in C$ , we define  $T_C(y^0, y^1)$  as the infimum of times required to pass from  $y^0$  to  $y^1$  under the state constraint  $C$  (with an unconstrained  $L^\infty$  control), with the agreement that  $T_C(y^0, y^1) = +\infty$  if  $y^1$  is not reachable from  $y^0$ . More precisely, if  $y^1$  is reachable from  $y^0$ , with  $L^\infty$  controls, we define

$$T_C(y^0, y^1) = \inf\{T > 0 \mid \exists u \in L^\infty((0, T), \mathbb{R}^m) \text{ s.t.}$$

the solution  $y(t)$  of (2) satisfies

$$y(T) = y^1 \text{ and } \forall t \in [0, T], y(t) \in C\}.$$

It is obvious that if  $r = \text{rank} B = n$  then  $T_C(y^0, y^1) = 0$  for any  $y^0$  and  $y^1$  belonging to a same connected component of  $C$ . More precisely, given any time  $T > 0$  and any  $C^1$ -path,  $\bar{y}$  such that  $\bar{y}(0) = y^0, \bar{y}(T) = y^1$  and  $\bar{y}(t) \in C$  for every  $t \in [0, T]$ , then any control  $\bar{u}$ , satisfying  $B\bar{u}(t) = \dot{\bar{y}}(t) - A\bar{y}(t)$ , steers the solution of (2) to  $y^1$  in time  $T$ . Hence, in what follows we assume that  $r < n$ .

As a first example (more details are given in Example 10 further), consider the linear control system

$$\dot{y}_1(t) = y_1(t) + u(t), \quad \dot{y}_2(t) = 2y_2(t) + u(t),$$

under the nonnegativity state constraints  $y_1(\cdot) \geq 0, y_2(\cdot) \geq 0$ , and take the terminal conditions  $y^0 = (1, 1/2)^\top$  and  $y^1 = (2, 1)^\top$ . Both points are steady-states,  $C = [0, +\infty)^2$  is convex and the Kalman rank condition is satisfied. Hence, it is possible to steer the system from  $y^0$  to  $y^1$  with a trajectory satisfying the state constraints (see Section 4.1). But we claim that this cannot be done in arbitrarily small time. Here, the value of the minimal time under the state constraint  $y(\cdot) \in C$  is  $T_C(y^0, y^1) = \ln(2)$ . In contrast, steering the control system from  $y^1$  to  $y^0$  in  $C$  can be done in arbitrarily small time, i.e., we have  $T_C(y^1, y^0) = 0$ .

The main result of the paper is the following.

**Theorem 1.** *Let  $C$  be a subset of  $\mathbb{R}^n$  and let  $y^0 \in C$ .*

- (i) *Let  $y^1 \in \hat{C} \setminus \{y^0\}$ . Assume that  $y^0 \in \hat{C}$  and there exists a steady state  $\bar{y} \in \hat{C}$ . If  $\bar{y}$  and  $y^1$  are in a same connected component of  $(\{y^0\} + \text{Ran} B) \cap \hat{C}$ , then  $T_C(y^0, y^1) = 0$ .*
- (ii) *Assume that  $C$  is bounded and let  $y^1 \in C \setminus \{y^0\}$ . If  $y^1 - y^0 \notin \text{Ran}(B)$  then  $T_C(y^0, y^1) > 0$ .*
- (iii) *Assume that*

$$C = \{y \in \mathbb{R}^n \mid \langle \ell, y \rangle = \ell_1 y_1 + \dots + \ell_n y_n \geq \beta\} \quad (3)$$

*(unilateral and affine state constraint) for some  $\beta \in \mathbb{R}$  and for some generic<sup>1</sup>  $\ell \in \mathbb{R}^n \setminus \{0\}$ .*

- *If  $r = \text{rank} B > 1$  then under a generic<sup>2</sup> condition on the pair  $(A, B)$  we have  $T_C(y^0, y^1) = 0$  for any  $y^0, y^1 \in \hat{C}$ .*
- *If  $r = 1$  or if the above generic condition is not satisfied then there exists an open subset  $C_1 \subset C$  such that  $T_C(y^0, y^1) > 0$  for every  $y^1 \in C_1$ .*

<sup>1</sup> The word generic means here that  $\ell$  belongs to some subset of  $\mathbb{R}^n \setminus \{0\}$  which is open and dense.

<sup>2</sup> The word generic means here that the pair  $(A, B)$  belongs to an open and dense subset of the set of matrices  $(A, B)$  with  $A$  (resp.  $B$ ) an  $n \times n$  (resp.  $n \times m$ ) matrix.

Note that, in the statement (i) of the theorem, when  $y^1 - y^0 \in \text{Ran}(B)$ , even if the segment  $[y^0, y^1]$  is contained in  $\tilde{C}$ , it may happen that  $T_C(y^0, y^1) > 0$  (see the example given in Section 2.6).

The statement (ii) says that imposing a bounded state constraint creates a positive minimal time. More strikingly, the statement (iii) shows that an unilateral (and thus, unbounded) state constraint may as well create a positive minimal time, depending on the position of the terminal points. It is interesting to note that, for such an unilateral state constraint, the positive minimal time property occurs generically only for  $m = 1$  (only one scalar control).

However, this theorem does not establish the existence of a control in the minimal time and the existence of such a control is open. As we will indicate further in Section 2.7, we can expect that a minimal time control exists in a wider class of controls.

An additional question discussed in this paper is: does the minimal time defined with  $L^\infty$  controls coincide with the minimal time defined with a wider class of controls?

The proof of Theorem 1, done in Section 2, consists of a series of very simple arguments consisting of reductions using Brunovsky normal forms. For the unilateral state constraint (3), it reduces our study to the investigation of a linear control system under a nonnegativity constraint on one of the controls.

The statement (iii) of Theorem 1 can be easily extended to the case where we consider  $k$  unilateral state constraints, i.e. with  $C = \{y \in \mathbb{R}^n \mid L^T y \geq \beta\}$ , with  $L$  an  $n \times k$  matrix and  $\beta \in \mathbb{R}^k$ . With similar arguments as the one used for the proof of Theorem 1, it is possible to show that

- If  $r = \text{rank } B > k$ , then under a generic condition on  $A, B$  and  $L$ , we have  $T_C(y^0, y^1) = 0$  for any  $y^0, y^1 \in C$ ;
- If  $m \leq k$ , then under a generic condition on  $A, B$  and  $L$ , there exists an open subset  $C_1 \subset C$  such that  $T_C(y^0, y^1) > 0$  for every  $y^1 \in C_1$ .

Since the proof of this result is a slight modification of the one of Theorem 1, and since this proof requires more technical notations, we did not provide here the proof of this result.

**Heuristic arguments and comments.** An intuition suggesting that the minimal controllability time may be positive is the following. We explain it by assuming that  $m = 1$ , i.e., in the case where the control is scalar; in this case the matrix  $B$  is a (nonzero) vector in  $\mathbb{R}^n$ . Since there is no constraint on the control  $u$ , one can use large control inputs, which behave like impulsive controls, (e.g., approximations of Dirac masses). In particular, in this sense, one can move almost instantaneously in the directions given by  $B$ , that is, parallel to  $B$ , by taking  $u(t) = M$  (or  $-M$ ) over a small time interval, with  $M > 0$  very large. For instance, if the system is at state  $y$  at the instant of time  $t$ , and if one takes an impulsive control input in the direction  $B$ , then one can move in arbitrarily small time to any point of the affine line  $y + \mathbb{R}B$ . But then, according to the shape of the set  $C$ , the state constraint  $y(\cdot) \in C$  may prevent the trajectory from moving too far along this line and may then constrain the motion, forbidding one to use such impulses that are not actually admissible because of the state constraint.

Now, in order to move along other directions, for instance, parallel to  $AB$ , one usually takes a succession of arcs:  $u = +M$ , then  $u = -M$ , over small time intervals, with  $M > 0$  very large. This corresponds to moving along Lie brackets (see Coron, 2007, Section 3.2 and comments page 133). Geometrically, this means that, in order to make one step in some direction  $AB$ , one needs to go first very far in the direction  $B$  and then maybe in the direction  $-B$ . This can indeed be done if there is no state constraint. But, as above, the state constraint  $y(t) \in C$  may forbid to be able to achieve such a motion.

When  $m > 1$ , these comments are still valid by replacing the vector  $B$  above by any nontrivial vector of  $\text{Ran}(B)$ , the range of the  $n \times m$  matrix  $B$ .

Of course, the above arguments do not make a rigorous proof but anyway suggest the possible occurrence of a positive minimal time due to state constraints, even if the state constraint is unilateral.

Since the controls are unconstrained, trajectories going from  $y^0$  to  $y^1$  can move arbitrarily quickly as long as they are in the interior of the authorized region  $C$  (in other words, outside of  $C$  jumps are allowed) but there is a “loss of time” along the boundary  $\partial C$ . This is easily understood by writing (at least locally)  $C = \{y \in \mathbb{R}^n \mid c(y) \leq 0\}$  for some function  $c : \mathbb{R}^n \rightarrow \mathbb{R}$  of class  $C^1$ : indeed, along a boundary arc, one has  $c(y(t)) = 0$  and by derivating in time we get

$$\langle \nabla c(y(t)), Ay(t) \rangle + \langle B^* \nabla c(y(t)), u(t) \rangle = 0.$$

Thus, along  $\partial C$ , the motion should be done in minimal time under this new mixed state and control constraint. For instance, if  $m = 1$  and if  $\langle \nabla c(y), B \rangle \neq 0$  for every  $y \in \partial C$  (meaning that the state constraint is of order one (Bonnard, Faubourg, Launay, & Trélat, 2003)), then the boundary control must be

$$u(t) = u(y(t)) = - \frac{\langle \nabla c(y(t)), Ay(t) \rangle}{\langle \nabla c(y(t)), B \rangle}$$

and generates a boundary arc that travels at finite speed (following the flow of  $\dot{y}(t) = Ay(t) + Bu(y(t))$ ), thus creating a positive minimal time. This situation is similar for higher-order state constraints where one needs to differentiate several times before making the control appear explicitly (see Bonnard et al., 2003) and in any case, since the value of the control cannot be arbitrarily large, this causes a “loss of time” along the boundary arc.

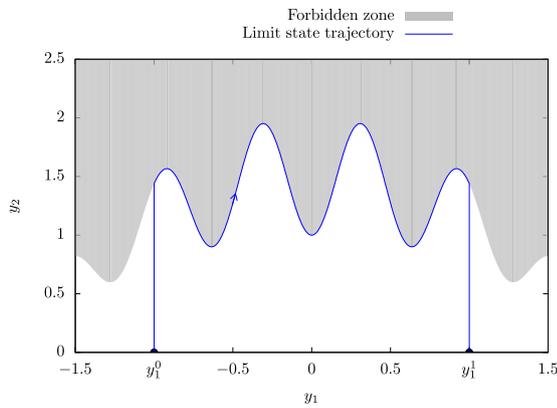

For 2D systems, the situation is quite well understood and this will be developed in Section 5. In the 2D case it is also easy to illustrate the above informal arguments. This is done on Fig. 1 (see also Remark 9, and Fig. 3, for more details on this computation). For this figure, we have considered the system  $\dot{y}_1 = y_2, \dot{y}_2 = u$ , under the state constraint  $y_2(t) \leq \varphi(y_1(t))$ , for some positive  $C^1$  function  $\varphi$ .

- (1) Since the initial point,  $(y_1^0, 0)^T$  is in the interior of the set of state constraints, one can move with arbitrarily large velocity in the direction generated by  $B = (0, 1)^T$ . At the formal limit, this corresponds to an impulse control (Dirac mass) at the initial time. This impulse is such that the trajectory instantaneously reaches the boundary of the state constraint, at the boundary point  $(y_1^0, \varphi(y_1^0))^T$  and the corresponding Dirac impulse control is  $\varphi(y_1^0)\delta_0$ .
- (2) The control is then tuned to follow the state constraint until the point  $(y_1^1, \varphi(y_1^1))^T$ . This causes a “loss of time”.
- (3) From the point  $(y_1^1, \varphi(y_1^1))^T$ , it is finally possible to instantaneously reach the target  $(y_1^1, 0)^T$  with a Dirac impulse control.

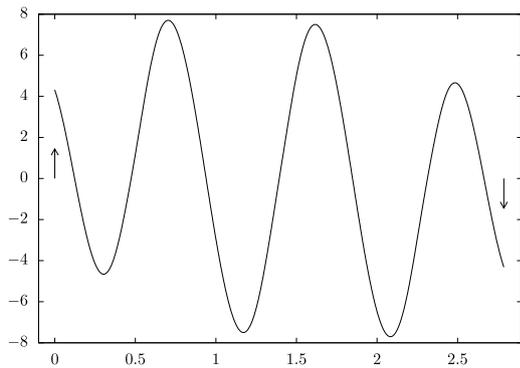

These rather informal considerations explain why a positive minimal time may be expected to occur, due to state constraints (even unilateral) and although there is no control constraint.

**Article organization.** The article is structured as follows:

- Theorem 1 is proved in Section 2.
- In Section 3 we provide several extensions of Theorem 1, considering nonlinear control-affine systems under unilateral state constraints.
- Section 4 is devoted to establishing several further facts: controllability in large time among the set of steady-states (Section 4.1); there is no classical control exactly at the minimal time (Section 4.2); the minimal time with unbounded controls is the limit of the minimal time under the additional control constraint  $|u(\cdot)| \leq M$  as  $M \rightarrow +\infty$  (Section 4.3).

(a) State trajectories in the *limit* case

(b) Control in the *limit* case (arrows stands for Dirac masses).

**Fig. 1.** Limit trajectories for the 2D Brunovsky system  $\dot{y}_1 = y_2, \dot{y}_2 = u$ , with initial point  $y^0 = (0, -1)^T$  and target  $y^1 = (0, 1)^T$ .

- In Section 5 we compute explicitly the minimal transfer time in 2D (Proposition 8) and we give several examples.
- Section 6 is a conclusion listing some open problems.

## 2. Proof of Theorem 1

In this section, we give the proof of Theorem 1. The statement (i) is proved in Section 2.1. For the other statements, we proceed in three steps (Sections 2.2–2.4). These steps are summarized in a concluding section (Section 2.5). We illustrative this result with an example in Section 2.6 and we give some additional comments on this proof in Section 2.7.

### 2.1. Proof of statement (i)

It suffices to prove that  $y^0$  (respectively,  $\bar{y}$ ) can be steered in arbitrarily small time to  $\bar{y}$  (respectively,  $y^1$ ). By reversing the time ( $t \mapsto T - t$ ), proving that  $\bar{y}$  can be steered to  $y^1$  in arbitrarily small time is equivalent to proving that  $y^1$  can be steered to  $\bar{y}$  in arbitrarily small time. Consequently, for the proof, we assume that  $y^1$  is a steady state,  $y^1 \neq y^0$ , and that there exists  $\bar{v} \in C^1([0, 1], \mathbb{R}^m)$  such that  $\bar{v}(0) = 0, y^0 + B\bar{v}(1) = y^1$  and for every  $s \in [0, 1], y^0 + B\bar{v}(s) \in \bar{C}$ .

For some  $M > 0$ , we take as control  $u^M(t) = M\dot{\bar{v}}(Mt)$ , for  $t \in [0, 1/M]$ . Then as  $M \rightarrow \infty$ , for every  $s \in [0, 1], y^M(s/M) \rightarrow y^0 + B\bar{v}(s)$ . This ensures that for  $M > 0$  large enough,  $y^M(t) \in \bar{C}$

for every  $t \in [0, 1/M]$  and  $y^M(1/M)$  is in a neighborhood of  $y^1$ . Using small time local controllability around  $y^1$ , we obtain that  $y^M(1/M)$  can be steered to  $y^1$  in some time  $\tau = \tau(M)$ , while the state constraint is preserved. In addition, since  $y^M(1/M)$  converges to  $y^1$  as  $M \rightarrow \infty$ , we also have that  $\tau(M)$  converges to 0 as  $M \rightarrow \infty$ . This ends the proof of statement (i) of Theorem 1.

### 2.2. First step: feedback equivalence and dynamic Brunovsky normal form

First of all, since no constraint is imposed on the control, one can perform a feedback equivalence in order to obtain a (sometimes called “dynamic”) Brunovsky normal form for (2).

We recall that the pair  $(A, B)$  is feedback equivalent to  $(\tilde{A}, \tilde{B})$  if there exist an invertible matrix  $P$  of size  $n \times n$ , an invertible matrix  $V$  of size  $m \times m$  and a matrix  $F$  of size  $m \times n$  such that  $P^{-1}(A+BF)P = \tilde{A}$  and  $P^{-1}BV = \tilde{B}$ . Feedback equivalence corresponds to make the changes of variables  $y = P\tilde{y}$  and  $u = Fy + V\tilde{u}$ , where  $\tilde{y}$  is the new state and  $\tilde{u}$  is the new control. The new control system is

$$\dot{\tilde{y}}(t) = \tilde{A}\tilde{y}(t) + \tilde{B}\tilde{u}(t). \tag{4}$$

Note that  $(\tilde{A}, \tilde{B})$  satisfies the Kalman condition as well, that the new state  $\tilde{y}(t)$  is submitted to the state constraint  $\tilde{y}(\cdot) \in P^{-1}C$ , and that the new control  $\tilde{u}(\cdot) \in \mathbb{R}^m$  is still unconstrained. In addition, if  $\bar{y}$  is a steady state for the system (2), then  $P^{-1}\bar{y}$  is a steady state as well for the system (4). For the unilateral and affine state constraint (3), the constraint  $\tilde{y}(\cdot) \in P^{-1}C$  gives  $\langle \tilde{\ell}, \tilde{y}(\cdot) \rangle \geq \beta$  with  $\tilde{\ell} = P^T \ell$ .

The multi-input Brunovsky normal form theorem (see, e.g., Sontag, 1998) asserts that, if  $(A, B)$  satisfies the Kalman condition and if  $\text{rank}(B) = r \leq m$  then the pair  $(A, B)$  is feedback equivalent to the pair of matrices given by

$$A = \begin{pmatrix} A_{k_1} & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & A_{k_r} \end{pmatrix} \tag{5a}$$

and

$$B = \begin{pmatrix} b_{k_1} & 0 & \cdots & 0 & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & \vdots & \vdots & \vdots & \vdots \\ \vdots & \ddots & \ddots & 0 & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & b_{k_r} & 0 & \cdots & 0 \end{pmatrix} \tag{5b}$$

where the indices  $k_i \in \{1, \dots, n\}$  ( $i \in \{1, \dots, r\}$ ) satisfy  $k_1 + \dots + k_r = n$  and where we have defined the matrices

$$A_k = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ \vdots & & & \ddots & 1 \\ 0 & \cdots & \cdots & \cdots & 0 \end{pmatrix}, \quad b_k = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix} \tag{6}$$

of respective sizes  $k \times k$  and  $k \times 1$  for any  $k \in \mathbb{N}^*$ . Here, we have dropped the tildes in order to keep a better readability. Writing  $y = (y_1, \dots, y_r) \in \mathbb{R}^{k_1} \times \dots \times \mathbb{R}^{k_r}$  and  $u = (u_1, \dots, u_m)^T$ , the control system (4) is

$$\dot{y}_i = A_{k_i}y_i + b_{k_i}u_i, \quad i = 1, \dots, r, \tag{7}$$

with unconstrained controls  $u_1, \dots, u_r$ .

This transformation has no impact on the minimal controllability time and the minimal time  $T_C(y^0, y^1)$  for the system (2) with state constraint  $C$  is equal to the minimal time  $T_C(P^{-1}y^0, P^{-1}y^1)$

for the system (4) with state constraint  $P^{-1}C$ . Let us also give the generic assumption on  $\ell$  mentioned in the statement (iii) of Theorem 1:

$P^T \ell$  is not a steady state for the system (2) with matrices  $A$  and  $B$  are given by (5).

In other words, we make the generic assumption that  $PP^T \ell$  is not a steady state for the system (2) in the initial coordinates.

Based on these considerations, we assume, without loss of generality, that the system (2) is already in Brunovsky form (i.e. the matrices  $A$  and  $B$  are given by (5) and  $\ell$  is not a steady state).

### 2.3. Second step: reduction by Goh transformation

Let us first explain the idea when there is only one block in (7), i.e., when  $r = 1$ . We have then the control system

$$\dot{y}_{1,1} = y_{1,2}, \dot{y}_{1,2} = y_{1,3}, \dots, \dot{y}_{1,k_1-1} = y_{1,k_1}, \dot{y}_{1,k_1} = u_1.$$

Since the control  $u_1$  is unconstrained, the Goh transformation consists of reducing the above system of one dimension by considering  $y_{1,k_1}$  itself as a new control. In other words, this is as if we would take  $u_1$  as Dirac masses and then allow  $y_{1,k_1}$  to have discontinuities. This well known idea, consisting in replacing the control by its primitive and then in considering part of the state as a new control, is referred to as the *Goh transformation*. Introduced in Goh (1966), this transformation has often been used to derive second-order necessary and/or sufficient conditions for optimality and is related to the notion of *cheap control* (see Bonnard & Chyba, 2003).

Let us now explain how this transformation has an impact on the state constraint  $y(\cdot) \in C$ . Assume that this state constraint only acts on the  $j_1 + 1$  first coordinates  $y_{1,1}, \dots, y_{1,j_1+1}$ . Then one can reiterate the Goh transformation  $k_1 - j_1$  times, until, indeed,  $y_{1,j_1+1}$  itself has become a control. Then, for the reduced control system in dimension  $j_1$ , where the state is  $z_1 = (y_{1,1}, \dots, y_{1,j_1})$  and the control is  $v_1 = y_{1,j_1+1}$ , the new constraint is  $(z_1(\cdot), v_1(\cdot)) \in C$ , which is now a *mixed state and control constraint*.

For instance, for the unilateral and affine state constraint (3), written here as  $\ell_{1,1}y_{1,1}(\cdot) + \dots + \ell_{1,k_1}y_{1,k_1}(\cdot) \geq \beta$  where  $\ell_i = (\ell_{i,1}, \dots, \ell_{i,k_i}) \in \mathbb{R}^{k_i}$ , the above assumption means that  $\ell_{1,j_1+2} = \dots = \ell_{1,k_1} = 0$ . Hence, at the end of the series of Goh transformations, we have obtained the mixed state and control constraint  $\ell_{1,1}y_{1,1}(\cdot) + \dots + \ell_{1,j_1}y_{1,j_1}(\cdot) + \ell_{1,j_1+1}v_1(\cdot) \geq \beta$ .

In general, doing so for each block in (7), we obtain that the minimal controllability time  $T_C(y^0, y^1)$  is not lower than the minimal time for steering the control system (living in lower dimension)

$$\dot{z}_i(t) = A_j z_i(t) + b_j v_i(t) \quad i = 1, \dots, s$$

from the initial point  $(z_1^0, \dots, z_s^0)$  to the final point  $(z_1^1, \dots, z_s^1)$  with unconstrained controls, under the mixed state and control constraint

$$(z_1(\cdot), v_1(\cdot), \dots, z_s(\cdot), v_s(\cdot)) \in C.$$

The novelty here is that, at the previous step we had a *pure state constraint*, and now due to the Goh transformation we have obtained a *mixed state and control constraint* indeed acting in a nontrivial way, in particular, on the controls  $v_i$ .

At this stage, the second point of the statement (ii) of the theorem easily follows, i.e., imposing a bounded state constraint creates a positive minimal time. This is so since the new controls  $v_1, \dots, v_s$  are bounded. This completes the proof of statement (ii) of Theorem 1.

Let us now establish the statement (iii), by considering the unilateral and affine state constraint (3). We denote  $\ell = (\ell_1, \dots, \ell_r) \in \mathbb{R}^{k_1} \times \dots \times \mathbb{R}^{k_r}$ , with indices  $k_i$  organized so that  $k_i = 1$  for  $i > s$  and  $k_i > 1$  for  $i \leq s$ . Then, the assumption that  $\ell$  is not a steady-state ensures the existence of  $i_0 \in \{1, \dots, s\}$  and  $j_0 \in \{2, \dots, k_{i_0}\}$  such

that the  $j_0$ th coefficient of  $\ell_{i_0}$  is nonzero. Without loss of generality, we fix  $i_0 = 1$ , we denote by  $j_0$  the index of the last nonzero coefficient of  $\ell_1$ , and set  $\gamma = \ell_{1,j_0}$  the value of this coefficient. By performing  $k_1 - j_0 + 1$  Goh transformations on the control  $u_1$ , we obtain that the minimal control time  $T_C(y^0, y^1)$  is not lower than the minimal time for steering the control system

$$\begin{aligned} \dot{z}_1(t) &= A_{j_0-1} z_1(t) + b_{j_0-1} v_1(t) \\ \dot{y}_i(t) &= A_{k_i} y_i(t) + b_{k_i} u_i(t) \quad i = 2, \dots, r \end{aligned} \tag{8}$$

from the initial point  $(z_1^0, y_2^0, \dots, y_r^0)$  to the final point  $(z_1^1, y_2^1, \dots, y_r^1)$  with controls  $v_1, u_2, \dots, u_r \in L^\infty(0, T)$  under the mixed state and control constraint

$$\langle \widehat{\ell}_1, z_1(\cdot) \rangle + \gamma v_1(\cdot) + \langle \ell_2, y_2(\cdot) \rangle + \dots + \langle \ell_r, y_r(\cdot) \rangle \geq \beta$$

where  $z_1$  (resp.,  $\widehat{\ell}_1$ ) is the vector consisting of the first  $j_0 - 1$  components of  $y_1$  (resp.,  $\ell_1$ ). Recall that the matrices  $A_k$  and  $b_k$  are defined by (6) for every  $k \in \mathbb{N}^*$ .

At this step, we have therefore reduced our initial problem to the minimal time problem for a linear control system with  $r$  scalar controls among which  $r - 1$  controls are unconstrained. More generally, we have shown that the minimal control time  $T_C(y^0, y^1)$  is not lower than the minimal time for

$$\begin{aligned} \dot{y}(t) &= Ay(t) + Bu(t) \\ \langle \alpha, y(\cdot) \rangle + \gamma u_1(\cdot) &\geq \beta, \end{aligned} \tag{9}$$

where the pair  $(A, B)$  satisfies the Kalman condition and  $\gamma \in \mathbb{R} \setminus \{0\}$ . Here,  $A$  (resp.  $B$  and  $\alpha$ ) is an  $N \times N$  matrix (resp.  $N \times r$  matrix and vector of  $\mathbb{R}^N$ ) with  $N = n - k_1 + j_0 - 1$ . In order to avoid new notations, we keep denoting  $n$  instead of  $N$  and  $m$  instead of  $r$ .

### 2.4. Third step: change of control

Considering (9), we replace the control  $u$  with the new control  $\bar{u}$  given by  $\bar{u}_1 = \langle \alpha, y \rangle + \gamma u_1 - \beta$  and  $\bar{u}_i = \gamma u_i$  for  $i > 1$  and we thus obtain the new control system

$$\begin{aligned} \dot{y}(t) &= \frac{1}{\gamma}(\gamma A - b_1 \alpha^T)y(t) + \frac{1}{\gamma}B\bar{u}(t) + \frac{\beta}{\gamma}b_1 \\ \bar{u}_i(\cdot) &\geq 0 \end{aligned}$$

where  $b_1$  is the first column of  $B$  and the control  $\bar{u} \in L^\infty((0, T), \mathbb{R}^m)$  is constrained to have a nonnegative first component. Let us also notice that the pair  $(\gamma A - b_1 \alpha^T, B)$  satisfies the Kalman condition.

At this step, we have reduced the constraint on the control to an *unilateral* (nonnegativity) constraint on the first component of the control.

Hence, without loss of generality, we consider the minimal time problem for the linear control system

$$\begin{aligned} \dot{y}(t) &= Ay(t) + Bu(t) + r \\ u_1(\cdot) &\geq 0 \end{aligned} \tag{10}$$

with  $A$  (resp.  $B$  and  $r$ ) an  $n \times n$  matrix (resp.  $n \times m$  matrix and vector of  $\mathbb{R}^n$ ) and the pair  $(A, B)$  satisfies the Kalman condition, with  $m$  scalar controls among which the  $m - 1$  last controls are unconstrained and the first control is subject to an unilateral (nonnegativity) constraint. In order to establish the statement (iii) of Theorem 1, we only need to prove that for every initial state  $y^0 \in \mathbb{R}^n$ , there exists a target state  $y^1 \in \mathbb{R}^n$  that cannot be reached in arbitrarily small time by a solution of (10) such that  $y(0) = y^0$ .

More precisely, given any time  $T > 0$  and any solution  $y$  of (10) such that  $y(0) = y^0$ , we have

$$y(T) \in \left( e^{TA}y^0 + \int_0^T e^{(T-t)A} r dt \right) + Acc^+(T)$$

where

$$Acc^+(T) = \left\{ \int_0^T e^{(T-t)A} B u(t) dt \mid u \in L^\infty((0, T), \mathbb{R}^m), u_1(\cdot) \geq 0 \right\}$$

is the set of accessible points with controls  $u$  having a nonnegative first component. It is easy to see that  $Acc^+(T)$  is a convex cone with vertex at 0 and that  $Acc^+(T_1) \subset Acc^+(T_2)$  if  $T_1 < T_2$ . It would be compact and evolve continuously with respect to  $T$  if there were to be a compact constraint on the controls (see Lee & Markus, 1967; Trélat, 2005); but here, we only have an unilateral constraint on  $u$ .

In the next lemma, we denote by  $b_1$  the first column of  $B$  and by  $\hat{B}$  the  $n \times (m - 1)$  matrix formed by the remaining columns of  $B$  (when  $m = 1$ , we have  $B = b_1$ ).

**Lemma 2.** *If  $m > 1$  and if the pair  $(A, \hat{B})$  satisfies the Kalman condition then  $Acc^+(T) = \mathbb{R}^n$  for every  $T > 0$ .*

*Otherwise, if  $m = 1$  or if the pair  $(A, \hat{B})$  does not satisfy the Kalman condition, then  $Acc^+(T)$  is a convex cone with vertex at 0, which is isomorphic to the positive quadrant of  $\mathbb{R}^n$  for  $T > 0$  small enough.*

We stress that this result is only valid in small time. Indeed, for  $N = 2$  consider the matrices

$$A = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad b = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

We have  $m = 1$ , and we claim that  $Acc^+(T) = \mathbb{R}^2$  for every  $T > 2\pi$ . Indeed, consider the corresponding control system and let it start at  $(0, 0)$  at time 0. On a first interval  $[0, \varepsilon]$  with  $\varepsilon > 0$  small, take  $u(t) = 1$ , so we steer the system to some point that is close but distinct from the origin. Then, take  $u = 0$  and wait: the corresponding trajectory runs at speed 1 along a circle centered at the origin. This is the way that in time greater than  $2\pi$  one can indeed reach any point of the plane.

This simple example shows that, although  $Acc^+(T)$  is a proper subset of  $\mathbb{R}^n$  for  $T > 0$  small, it may evolve discontinuously in time and become equal to the whole  $\mathbb{R}^n$  for  $T > T_0$ , for some  $T_0 > 0$ .

**Proof.** The first claim is clear. Let us prove the second claim. Consider first the case  $m = 1$ . We consider the system  $\dot{y} = Ay + b_1 u_1$ . In order to prove that  $Acc^+(T)$  is isomorphic to the positive quadrant, one needs to prove that  $Acc^+(T)$  and its complement contain a nonempty open set. The fact that  $Acc^+(T)$  contains a nonempty open set follows from the Kalman condition on the pair  $(A, b_1)$ . In order to prove that the complement of  $Acc^+(T)$  contains a nonempty open set for small enough time  $T$ , let us prove that  $-Acc^+(T) \setminus \{0\}$  is contained in the complement of  $Acc^+(T)$ , i.e.,  $-Acc^+(T) \cap Acc^+(T) = \{0\}$  for  $T > 0$  small enough. Assume by contradiction that for every  $T > 0$  there exists  $y^{1,T} \neq 0$  such that  $y^{1,T} \in -Acc^+(T) \cap Acc^+(T)$ . Then there exist two nontrivial nonnegative controls  $w_1^T$  and  $v_1^T$  such that

$$\begin{aligned} y^{1,T} &= \int_0^T e^{(T-t)A} b_1 w_1^T(t) dt \\ &= - \int_0^T e^{(T-t)A} b_1 v_1^T(t) dt. \end{aligned}$$

We have  $w_1^T \neq v_1^T$  (because  $y^{1,T} \neq 0$ ) and hence the nontrivial nonnegative control  $u_1^T = w_1^T + v_1^T$  is such that  $\int_0^T e^{(T-t)A} b_1 u_1^T(t) dt = 0$ . Hence,

$$\begin{aligned} 0 &< \int_0^T u_1^T(t) dt = \frac{-1}{|b_1|^2} \int_0^T b_1^T (e^{(T-t)A} - I_n) b_1 u_1^T(t) dt \\ &\leq \sup_{t \in [0, T]} \frac{|b_1^T (e^{tA} - I_n) b_1|}{|b_1|^2} \int_0^T u_1^T(t) dt. \end{aligned}$$

Since  $\sup_{t \in [0, T]} |b_1^T (e^{tA} - I_n) b_1| \rightarrow 0$  as  $T \rightarrow 0$ , there exists  $T > 0$  small enough such that  $\int_0^T u_1^T(t) dt < \int_0^T u_1^T(t) dt$ . This raises a contradiction and the claim is proved for  $m = 1$ .

Let us now assume that  $m > 1$  and that  $(A, \hat{B})$  does not satisfy the Kalman condition. In this case we have  $Acc^+(T) = Acc_1^+(T) + \widehat{Acc}(T)$  where

$$Acc_1^+(T) = \left\{ \int_0^T e^{(T-t)A} b_1 u_1(t) dt \mid u_1 \in L^\infty(0, T), u_1(\cdot) \geq 0 \right\},$$

is the set of points accessible with nonnegative controls  $u_1$  and where

$$\widehat{Acc}(T) = \left\{ \int_0^T e^{(T-t)A} \hat{B} \hat{u}(t) dt \mid \hat{u} \in L^\infty((0, T), \mathbb{R}^{m-1}) \right\},$$

is the set of accessible points with (unconstrained) controls  $u_2, \dots, u_m$ . The set  $\widehat{Acc}(T)$  is independent of  $T$  because there is no constraint on  $\hat{u}$  and is a proper subspace of  $\mathbb{R}^n$  because the pair  $(A, \hat{B})$  does not satisfy the Kalman condition. Since the pair  $(A, (\hat{B} \mid b_1))$  satisfies the Kalman condition, it follows that  $Acc_1^+(T) \setminus \widehat{Acc}(T)$  is nonempty for every  $T > 0$ . Similar arguments to the one used for the case  $m = 1$  show that there exists  $T > 0$  small enough (such that  $\sup_{t \in [0, T]} |b_1^T (e^{tA} - I_n) b_1| < |b_1|^2$ ) such that  $-y_1^1 \notin Acc_1^+(T)$  for every  $y_1^1 \in Acc_1^+(T) \setminus \widehat{Acc}(T)$ .

Let us now pick such a time  $T > 0$ . For every  $y_1^1 \in Acc_1^+(T) \setminus \widehat{Acc}(T)$ , we have  $-y_1^1 \notin Acc_1^+(T)$ . This ensures that  $-y_1^1 \notin Acc^+(T)$ . This last claim can be proved by contradiction, if  $-y_1^1 \in Acc^+(T)$ , then there exist  $x_1 \in Acc_1^+(T)$  and  $\hat{x} \in \widehat{Acc}(T)$  such that  $-y_1^1 = x_1 + \hat{x}$ , consequently, we have  $-x_1 = y_1^1 + \hat{x} \in Acc^+(T)$ , but since  $x_1 \in Acc_1^+(T)$ , we necessarily have  $x_1 \in Acc_1^+(T) \cap \widehat{Acc}(T)$  and in particular,  $y_1^1 = -x_1 - \hat{x} \in \widehat{Acc}(T)$ , leading to a contradiction with  $y_1^1 \in Acc_1^+(T) \setminus \widehat{Acc}(T)$ .

Since  $Acc^+(T)$  is open in  $\mathbb{R}^n$  (this is due to the Kalman condition on  $(A, (b_1 \mid \hat{B}))$ ) and since  $\widehat{Acc}(T)$  is a proper subspace of  $\mathbb{R}^n$ , we have  $Acc^+(T) \setminus \widehat{Acc}(T)$  is a nonempty open set of  $\mathbb{R}^n$ . In order to conclude the proof of this lemma, we are now going to show that  $-Acc^+(T) \setminus \widehat{Acc}(T)$  is included in the complement of  $Acc^+(T)$ . Picking any point  $y^1 \in Acc^+(T) \setminus \widehat{Acc}(T)$ , we write  $y^1 = y_1^1 + \hat{y}^1$  with  $y_1^1 \in Acc_1^+(T) \setminus \widehat{Acc}(T)$  and  $\hat{y}^1 \in \widehat{Acc}(T)$ . Assume by contradiction that  $-y^1 \in Acc^+(T)$ , then there exist  $x_1 \in Acc_1^+(T)$  and  $\hat{x} \in \widehat{Acc}(T)$  such that  $-y^1 = x_1 + \hat{x}$ . This ensures that  $-y_1^1 = x_1 + \hat{y}^1 + \hat{x} \in Acc^+(T)$ . This leads to a contradiction with  $y_1^1 \in Acc_1^+(T) \setminus \widehat{Acc}(T)$  and this gives the claim.  $\square$

The result of Lemma 2 explains well why for every initial state there exist target points that cannot be reached in arbitrarily small time. More precisely, in the second alternative of the lemma, one has to wait a time  $T > 0$  such that  $y^1 - e^{TA} y^0 - \int_0^T e^{(T-t)A} r dt \in Acc^+(T)$ .

### 2.5. Conclusion of the proof

Let us summarize the three steps above for the proof of statement (iii) of Theorem 1.

- (1) We use a feedback equivalence to set the system (2) in Brunovsky form. This has no impact on the minimal controllability time.
- (2) We make a Goh transformation on a well chosen control to obtain a control system of the form (9) with mixed state and control constraint. The minimal transfer time for this new

system is lower than the initial minimal controllability time  $T_C(y^0, y^1)$ .

(3.a) We give conditions on the matrices  $A$  and  $B$  of (9) ensuring that there always exists a target such that the minimal time to reach it is positive. Actually, the minimal time is positive if the coefficients of  $\ell$  satisfy some polynomial condition. In particular, if  $\ell_2 = \dots = \ell_r = 0$  then the minimal time is positive. This proves the second point of statement (iii) of Theorem 1.

(3.b) In order to establish the first point of statement (iii) of Theorem 1, we will build a control for the reduced system (8) without using the control  $v_1$ . More precisely,  $v_1$  is going to be chosen arbitrarily so that the terminal conditions of the original system (2) are satisfied. Let us first recall that  $v_1$  stands for the  $j_0$ th coefficient of  $y_1$  and the  $k$ th derivative of  $v_1$  stands for the  $(j_0 + k)$ th coefficient of  $y_1$ . Let us also notice that the derivatives of  $v_1$  can be interpreted in terms of the derivatives of the control  $u_1$  appearing in (10) (in fact, we have  $u_1 = \langle \alpha, y \rangle + \gamma v_1 - \beta$ ). Now from Lemma 2, controllability of the reduced system (9) can be obtained only by using the control  $\hat{u} = (u_2, \dots, u_r)^T$ . In addition, we can impose that the derivatives of  $\hat{u}$  vanish at the initial and final times. This ensures that the derivatives at time 0 and  $T$  of  $u_1$  can be tuned independently of  $\hat{u}$ . By assumption, the initial and final conditions  $y^0$  and  $y^1$  are interior points of  $C$ . Consequently, we can build a  $C^\infty$  function  $u_1$  such that  $u_1 \geq 0$  with all derivatives of  $u_1$  given at time 0 and  $T$ . This system (with  $u_1$  imposed) can be controlled in time  $T > 0$  with a control  $\hat{u}$  of which all derivatives are equal to 0 at the initial and final times. Now we pick as control for the original system (2) the control  $(u_1^{(N)}, \hat{u})$ , where  $N$  is the number of Goh transformations. With this control, the solution of (2) satisfies the state constraint and reaches the target  $y^1$  in time  $T > 0$ . This ends the proof of the first point of the statement (iii), since  $T > 0$  can be arbitrarily small.

2.6. Example

To end this section, we give an example illustrating the second and third steps of the proof above. We consider the control system:

$$\dot{y}_1 = y_2, \quad \dot{y}_2 = y_3, \quad \dot{y}_3 = u, \tag{11}$$

under the state constraint  $y_3(t) \geq -1$ , i.e.  $C = \mathbb{R} \times \mathbb{R} \times [-1, \infty)$ . This system is already in Brunovsky form, consequently, the first step is trivial.

The second step is a Goh transformation leading to the reduced control system

$$\dot{y}_1 = y_2, \quad \dot{y}_2 = v,$$

under the control constraint  $v(t) \geq -1$ .

In the third step, we change the control and we set  $w(t) = v(t) + 1$ , thus considering the control system

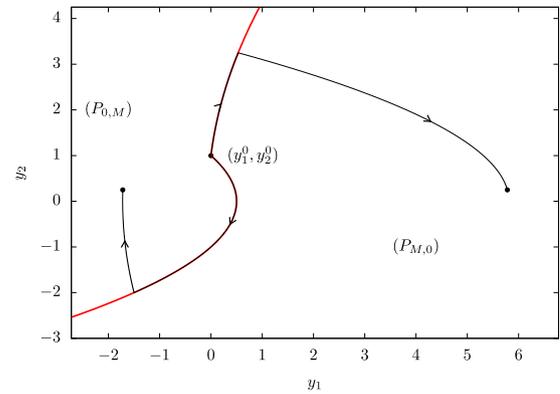

$$\dot{y}_1 = y_2, \quad \dot{y}_2 = w - 1,$$

under the control constraint  $w(t) \geq 0$ .

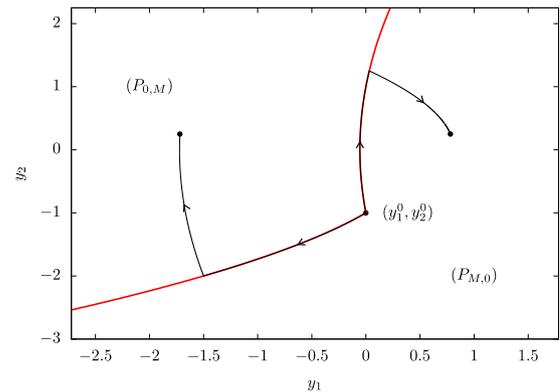

To compute the minimal time for this control problem, we add the control constraint  $w \leq M$  with  $M$  destined to tend to  $+\infty$ . According to Lee and Markus (1967, Theorem 20 p. 143), the time optimal control takes its values in  $\{0, M\}$  and has at most one switch. The following possible control strategies are given in Fig. 2 for two types of initial conditions.

Taking the limit  $M \rightarrow \infty$ , we obtain:

- (1) if  $y_2^0 > 0$  and if the target  $(y_1^1, y_2^1)$  is different from the initial condition  $(y_1^0, y_2^0)$  then the minimal time required to reach the target with the control constraint  $w(t) \geq 0$  is positive;

(a) Different types of optimal state trajectories with  $y_2^0 > 0$ .

(b) Different types of optimal state trajectories with  $y_2^0 < 0$ .

Fig. 2. We take  $M = 10$ . The zones  $(P_{0,M})$  and  $(P_{M,0})$  are delimited by the red lines. When the target is in the zone  $(P_{0,M})$  (respectively,  $(P_{M,0})$ ), then the optimal control strategy is to take the control  $w$  equal to 0 and then  $M$  (respectively,  $M$  and then 0). Examples of trajectories are plot in black. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

- (2) if  $y_2^0 \leq 0$ , if the target  $(y_1^1, y_2^1)$  does not belong to the segment  $\{y_1^0\} \times [y_2^0, -y_2^0]$ , then the minimal time required to reach the target with the control constraint  $w(t) \geq 0$  is positive, otherwise it is 0.

Going back to the original system (11), we obtain that  $T_C(y^0, y^1)$  can vanish if  $y_1^1 = y_1^0$  and  $y_2^1 = y_2^0$  or if  $y_1^1 = y_1^0, y_2^1 \leq 0$  and  $y_2^1 \in [y_2^0, -y_2^0]$ . Of course, due to the reduction procedure, we ignore the conditions on the last component  $y_3$  of  $y$  and at this step nothing ensures that the minimal time required to steer the original system from  $y^0 = (y_1^0, y_2^0, y_3^0)^T$  to  $y^1 = (y_1^1, y_2^1, y_3^1)^T$  is equal to the minimal time required to steer the reduced system from  $(y_1^0, y_2^0)^T$  to  $(y_1^1, y_2^1)^T$ .

Let us also illustrate on this system, the condition given in the first point of the statement (ii) of Theorem 1 in order to have  $T_C(y^0, y^1) = 0$ . More precisely, we give an example of initial and final conditions  $y^0$  and  $y^1$  such that  $y^1 - y^0 \in \text{Ran } B$  (but do not fulfill the first point of statement (ii) of Theorem 1) and we show that  $T_C(y^0, y^1) > 0$ . Namely, take  $y^0 = (0, 1, 0)^T$  and  $y^1 = (0, 1, 1)^T$ .

Let us prove that, if  $u \in L^\infty(0, T)$  is a classical  $L^\infty$  control steering  $y^0$  to  $y^1$  in time  $T$  then we must have  $T \geq 1$ . This positive minimal time is due to the fact that  $y_2(t)$  has to take some non-positive value. Indeed, assume by contradiction, that for every  $t \in [0, T]$ , we have  $y_2(t) > 0$ , then  $y_1(T) = \int_0^T y_2(t) dt > 0$ , hence

this control does not fulfill the target requirements. Consequently, there exists  $\tau \in [0, T]$  such that  $y_2(\tau) \leq 0$ . But, since  $y_2(t) = 1 + \int_0^t y_3(s) ds$ , and since  $y_3(s) \geq -1$ , for every  $t > 0$ , we have  $y_2(t) \geq 1 - t$ . Therefore, the first time instant  $\tau$  such that  $y_2(\tau) \leq 0$  cannot be lower than 1. This proves that  $T_C(y^0, y^1) \geq 1$ .

Let us also notice that with a Dirac mass located at the initial time the target  $y^1$  is instantaneously reached.

### 2.7. Additional comments

- In [Theorem 1](#), we only give the explicit minimal controllability time in the statement (i) and in the first point of statement (iii) and the minimal time is 0. When the assumption of the statement (i) is not completely satisfied (i.e.  $y^1 - y^0 \in \text{Ran } B$  but there does not exist a steady state in  $\{y^0\} + \text{Ran } B$ ), then as we can see in the example above, the minimal time may be positive.
- In the proof of [Theorem 1](#), we show that the minimal controllability time  $T_C(y^0, y^1)$  is non lower than the minimal controllability time of a reduced system with an unilateral control constraint. Let us point out that nothing ensures that these two minimal times coincide. In particular, in the example above, we show that the minimal controllability time of the reduced system is zero for some well chosen terminal conditions, but the minimal controllability time  $T_C(y^0, y^1)$  for the initial system is positive. Consequently, we cannot expect to have equality of the two times. Let us also mention that, in the only examples (showing this gap phenomenon) we have been able to build, the minimal controllability time for the reduced system is zero. Hence, we do not know if this gap appears in more general situations.
- A problem that has not been tackled in this proof is the existence of a minimal time control. As we will see further in [Proposition 6](#), generically there does not exist a classical  $L^\infty$  control in time  $T_C(y^0, y^1)$ . However, we expect that a control exists in a wider class. If there exists a minimal time control for the reduced system, then a strategy to build a minimal time control would be to take as original control the  $N$ th derivatives of the time optimal control for the reduced system ( $N$  being the number of Goh reductions that has been performed to obtain the reduced system). Of course, we expect that this control belongs to some space of distributions. To properly define a solution of the system with such irregular controls, we can use the transposition method (as done in [Lohéac, Trélat, and Zuazua \(0000\)](#)). In addition, with this control, the state might also be a distribution and we have to be careful with the definition of the state constraint  $y(t) \in C$ . However, when the state constraint is affine (as it is in the statement (iii) of [Theorem 1](#)), this should not be a problem.
- One last point is that with this new irregular control, there is no reason that the terminal conditions be fulfilled. In particular, in the Brunovsky form, the last part of the state will not be reached. However, this might be overcome by adding some Dirac masses (and/or derivatives of Dirac masses) at the initial and final times.
- The previous point is related with the following question: does the minimal time  $T_C(y^0, y^1)$  defined with  $L^\infty$  controls coincide with the minimal time defined with controls chosen in a wider class? To address this issue, a first step could be to consider Radon measure controls instead of  $L^\infty$  controls, this ensures that the corresponding state trajectory belongs to  $L^\infty$  and hence the state constraint  $y(t) \in C$  still makes sense. But as we can see in the example of [Section 2.6](#), the target state  $(0, 1, 1)^T$  can be reached instantaneously from the initial state  $(0, 1, 0)^T$  with a Dirac impulse whereas

this requires a waiting time greater than 1 when using classical  $L^\infty$  controls. Consequently, the minimal control time with Radon measure controls may differ from the minimal time with  $L^\infty$  controls. The study of conditions ensuring that these two minimal controllability times coincide is an interesting problem which would deserve more attention. We refer to [Gamkrelidze, 1978](#); [Warga \(1972\)](#) for studies of a possible gap of the value functions, respectively, associated to classical  $L^\infty$  controls or to relaxed measure controls.

## 3. Extensions of [Theorem 1](#)

### 3.1. Arbitrary unilateral state constraints

In the statement (iii) of [Theorem 1](#), we have considered the unilateral affine state constraint (3). If, instead, we consider a nonlinear unilateral state constraint of the form  $c(y(t)) \geq 0$  for some function  $c : \mathbb{R}^n \rightarrow \mathbb{R}$  of class  $C^1$ , then the first and the second steps in [Section 2](#) can be achieved as well.

Let us assume that  $m = 1$  (only one scalar control) and let us be more precise. In the second step, Goh transformations are made until we come up with a mixed state and control constraint of the form  $c(z(\cdot), v(\cdot)) \geq 0$ , instead of the linear one in (9). To perform the third step, we assume that  $\frac{\partial c}{\partial v} \neq 0$ . Then, by the implicit function theorem, at least locally this constraint can be written in the form  $\varphi(z(\cdot)) + v(\cdot) \geq 0$  (for some  $C^1$  function  $\varphi$ ), and then one can set  $\bar{v} = \varphi(z) + v$  as a new control. But then, instead of (10), we obtain the new control system

$$\begin{aligned} \dot{z}(t) &= Az(t) - b\varphi(z(t)) + b\bar{v}(t) = f(z(t)) + b\bar{v}(t), \\ \bar{v}(\cdot) &\geq 0, \end{aligned}$$

which is not linear anymore. The analysis done in the third step of [Section 2](#) can still be done with only slight changes, in small time (replace  $e^{tA}$  with the flow  $e^{t\tilde{f}}$ ). We do not provide details. We obtain here that, for generic functions  $c$  and for  $r = 1$ , there exists an open subset  $C_1 \subset C$  such that  $T_C(y^0, y^1) > 0$  for every  $y^1 \in C$ .

### 3.2. Nonlinear control-affine systems

Instead of considering the linear control system (2), we now consider the more general control-affine system

$$\dot{y}(t) = f(y(t)) + \sum_{i=1}^m u_i(t)g_i(y(t)), \tag{12}$$

where  $f$  and the  $g_j$ 's are smooth vector fields in  $\mathbb{R}^n$ . We consider the optimal control problem of steering in minimal time the control system (12) from a given  $y^0 \in C$  to some given  $y^1 \in C$ , without control constraint but under the state constraint  $y(\cdot) \in C$ .

Then the analysis done in [Section 2](#) can still be performed with few changes under appropriate assumptions. There exist indeed nonlinear versions of the Brunovsky normal form: in [Isidori \(1995\)](#), feedback equivalence with a linear control system is given under certain Lie bracket conditions (see also [Bonnard, Caillaud, & Trélat, 2007](#); [Bonnard & Chyba, 2003](#)). Precisely, defining

$$G_i(y) = \text{Span}\{\text{ad}^k f, g_j(y) \mid k = 0, \dots, i, j = 1, \dots, m\}$$

at any point  $y \in \mathbb{R}^n$  for  $i = 0, \dots, n-1$ , it is stated in [Isidori \(1995, Theorem 5.2.3 page 233\)](#) that if all  $G_i$ 's have constant dimension, if  $\dim G_{n-1} = n$  and if  $G_i$  is involutive for  $i = 0, \dots, n-2$  then there exists a (nonlinear) dynamic change of coordinates in which the system (12) can be written as a linear autonomous control system (2). This result is then applied in the first step of [Section 2](#), the other steps are then unchanged.

We obtain that, for  $C$  bounded and, under the above Lie bracket assumptions, if  $y^1 - y^0 \notin G_0(y^0)$  then  $T_C(y^0, y^1) > 0$ . This generalizes the statement (ii) of Theorem 1. We also obtain a generalization of the statement (iii), at least for  $r = 1$  and for generic constraints as in Section 3.1. Finally, similarly to the statement (i) of Theorem 1, if there exists a steady state  $\bar{y} \in \hat{C}$  such that the small time local controllability property holds at this point and if  $y^0, y^1$  and  $\bar{y}$  belong to the interior of  $C$  and  $y^1$  and  $\bar{y}$  are in a same component of  $(\{y^0\} + G_0(y^0)) \cap \hat{C}$ , then  $T_C(y^0, y^1) = 0$ .

It is interesting to notice that, because of the involutivity assumption, the above conditions on the Lie brackets are (by far) nongeneric. They generalize the case of  $f(y) = Ay$  and  $g_i(y) = b_i \in \mathbb{R}^n$ .

At the opposite, under the generic (in the sense of Whitney) condition that the Lie algebra  $\text{Lie}(g_1, \dots, g_m)$  generated by the vector fields  $g_i$  is equal to  $\mathbb{R}^n$  (Lie Algebra Rank Condition, also called Chow condition or Hörmander assumption), we claim that  $T_C(y^0, y^1) = 0$  for all  $y^0, y^1 \in \hat{C}$ . Indeed, under this generating Lie bracket assumption (which requires that  $m > 1$ ), given any path in  $\mathbb{R}^n$  joining  $y^0$  to  $y^1$  and given any tubular neighborhood  $V$  of this path, one can find a control steering the system (12) from  $y^0$  to  $y^1$  in arbitrarily small time with a corresponding trajectory remaining in  $V$  (see, e.g., Jurdjevic, 1997, Chapter 4). This fact generalizes the statement (iii) of Theorem 1 for the case  $r > 1$ .

For  $m = 1$  (only one scalar control), the situation is more complex. We have seen above that, under a nongeneric condition on the Lie brackets, the system is linearizable. But for generic vector fields  $(f, g_1)$ , the control system is not linearizable and actually new phenomena appear, which are typical of nonlinear systems. In particular, as soon as  $n \geq 3$ , singular trajectories do occur in a generic way (see Bonnard et al., 2007; Bonnard & Chyba, 2003) and under an open condition they are moreover time optimal.

Let us be more precise. Assuming that  $n \geq 3$  and that  $m = 1$ , there always exists at least one singular trajectory  $y(\cdot)$ , “singular” meaning that the linearized control system along  $y(\cdot)$  is not controllable. Now, along  $y(\cdot)$  we make the following generic assumptions: the set  $K(t) = \{\text{ad}^{k_f} g_1(y(t)) \mid k \in \mathbb{N}\}$  is of codimension one in  $\mathbb{R}^n$  and  $[g_1, [g_1, f]](y(t)) \notin K(t)$  along the trajectory  $y(\cdot)$ . Under an additional sign condition meaning that the latter vector field points in a certain direction with respect to the hyperplane  $K(t)$ , it is proved in Bonnard and Chyba (2003, Chapter 10.8, Prop. 96) that there exists a tubular neighborhood of  $y(\cdot)$  in which any minimal time trajectory is the concatenation of  $y(\cdot)$  with some jumps at the initial and at the final time. In other words, such a trajectory steering the system from  $y^0$  to  $y^1$  has a first jump, at time  $t = 0$ , to join the curve  $y(\cdot)$ , then it follows the singular trajectory  $y(\cdot)$  (and it must do so with a finite speed), and makes a final jump at the final time to reach the point  $y^1$ .

It is noticeable that this structure is the one encountered in the turnpike phenomenon (see (Trélat & Zuazua, 2015)). In any case, in this picture, time is lost along the singular trajectory. This is a new phenomenon with respect to the linear case where singular trajectories do not occur.

We summarize the above discussion in the following theorem.

**Theorem 3.** Let  $C$  be a subset of  $\mathbb{R}^n$  and let  $y^0 \in C$ .

- (i) Let  $y^1 \in C \setminus \{y^0\}$ . Assume that  $y^0 \in \hat{C}$  and that there exists a point  $\bar{y} \in \hat{C}$  at which small time local controllability holds. If  $\bar{y}$  and  $y^1$  are in a same connected component of  $(y^0 + G_0(y^0)) \cap \hat{C}$  then  $T_C(y^0, y^1) = 0$ .
- (ii) Assume that  $C$  is bounded and let  $y^1 \in C$ . If  $y^1 - y^0 \notin G_0(y^0)$ , if  $\dim G_i$  is constant for  $i = 0, \dots, n-1$ , if  $\dim G_{n-1} = n$  and if  $G_i$  is involutive for  $i = 0, \dots, n-2$  (nongeneric assumptions) then  $T_C(y^0, y^1) > 0$ .
- (iii) Assume that  $\text{Lie}(g_1, \dots, g_m) = \mathbb{R}^n$  (generic assumption, requiring that  $m > 1$ ). Then  $T_C(y^0, y^1) = 0$  for all  $y^0, y^1 \in \hat{C}$ .

- (iv) For  $m = 1$  and  $n \geq 3$ , under generic assumptions on the vector fields, if the subset  $C$  contains singular curves then there exists an open set of terminal conditions  $(y^0, y^1)$  for which  $T_C(y^0, y^1) > 0$ .

This theorem remains a bit informal but it is difficult to be more precise without entering into many technical considerations and this is not our aim here. As already explained, our main objective is to show that adding state constraints in an unconstrained control problem may create a positive minimal time.

## 4. Further facts

### 4.1. Steady-state controllability under state constraints

**Definition 4.** A point  $\bar{y} \in C$  is a steady-state if there exists  $\bar{u} \in \mathbb{R}^m$  such that  $A\bar{y} + B\bar{u} = 0$ .

For instance, when  $C = [0, +\infty)^n$ , a necessary and sufficient condition ensuring that any point of  $C$  is a steady-state is that

$$\text{Ran } B \cap \text{Cone}^+(a_1, \dots, a_n) \neq \emptyset$$

where  $a_1, \dots, a_n$  are the vectors of  $\mathbb{R}^n$  that are the columns of  $A$  and  $\text{Cone}^+(a_1, \dots, a_n)$  is the positive cone generated by these vectors.

Steady-states are particularly interesting because a connectedness assumption ensures that one can pass from any steady-state to any other one, while remaining in  $C$ , in large enough time. This assumption is the following:

Steady-state connectedness assumption:

Let  $y_0$  and  $y_1$  be two steady-states in  $C$ . We assume that there exists a path of steady-states  $\tau \mapsto \bar{y}(\tau)$ ,  $0 \leq \tau \leq 1$ , such that  $\bar{y}(0) = y^0$  and  $\bar{y}(1) = y^1$  and such that  $\bar{y}(\tau) \in \hat{C}$  for every  $\tau \in [0, 1]$ .

Here,  $\hat{C}$  is the interior of  $C$ . Note that, since the system is linear, if  $C$  is convex then, given any steady-states  $y^0$  and  $y^1$  in  $\hat{C}$ ,  $\tau \mapsto \bar{y}(\tau) = (1-\tau)y^0 + \tau y^1$  is a path of steady-states contained in  $\hat{C}$  and thus the above steady-state connectedness assumption is satisfied.

**Lemma 5.** Under the Kalman condition (1) and under the steady-state connectedness assumption, given any two steady-states  $y^0, y^1 \in \hat{C}$ , there exist  $T > 0$  (sufficiently large) and  $u \in L^\infty((0, T), \mathbb{R}^m)$  such that the corresponding solution  $y$  of (2) satisfies  $y(T) = y^1$  and  $y(t) \in C$  for every  $t \in [0, T]$ .

The proof consists of applying a local controllability argument (ensuring that the trajectory remains in  $C$ ), repeatedly along the path of steady-states, and one gets the conclusion by compactness. We do not provide any details. Notice that, based on such arguments, quasi-static control strategies have been implemented in Coron and Trélat (2004, 2006) in view of controlling nonlinear heat and wave equations on steady-states. Let us also refer to (Pighin & Zuazua, 2018) where this quasi-static control strategy has been used for the control of semi-linear heat equation under nonnegative state constraint.

### 4.2. No classical $L^\infty$ control at the minimal time

**Proposition 6.** Assume that either  $y^0$  or  $y^1$  belongs to  $\hat{C}$  and that  $T_C(y^0, y^1) \in (0, +\infty)$ . Then, exactly at  $T = T_C(y^0, y^1)$ , there does not exist any classical control  $u \in L^\infty((0, T), \mathbb{R}^m)$  steering the system (2) from  $y^0$  to  $y^1$  in time  $T$ .

This result ensures that the minimal time cannot be reached with  $L^\infty$  controls as soon as the initial point or the target point is in the interior of the set of state constraints. One can easily build examples, where the minimal time is reached with  $L^\infty$  controls. But this requires that the initial point and target point are in a same connected component of the boundary of the constraint set.

However, when  $y^0$  or  $y^1$  belong to  $\mathring{C}$ , one can wonder whether the minimal time can be reached with impulse controls in the space of distributions. This issue has been discussed in Section 2.7.

**Proof.** Reversing the time if necessary, we can assume that  $y^0 \in \mathring{C}$ . Let  $\varepsilon_0 > 0$  be such that the open ball  $B(y^0, \varepsilon_0)$  is contained in  $C$ .

Let us assume, by contradiction, that there exists a control  $\underline{u} \in L^\infty((0, T_C), \mathbb{R}^m)$  steering  $y^0$  to  $y^1$ . We set  $\underline{M} = \|\underline{u}\|_{L^\infty}$ . Let  $\tau \in (0, T_C]$  be such that  $\|e^{tA} - I_n\| \|y^0\| + (M+1)\|B\| \int_0^\tau \|e^{(t-s)A}\| ds < \varepsilon_0$  for every  $t \in [0, \tau]$ . The positive time instant  $\tau$  is defined so that for every control  $u \in L^\infty((0, \tau), \mathbb{R}^m)$  satisfying  $\|u\|_{L^\infty} \leq \underline{M} + 1$ , the solution of (2) satisfies  $y(t) \in C$  for every  $t \in [0, \tau]$ . We set  $\bar{y} = y(\tau; \underline{u})$ , the solution at time  $\tau$  of (2) with control  $\underline{u}$ . Since  $\underline{u}$  is assumed to be time optimal, it follows that  $\tau$  is the minimal time required time to steer  $y^0$  to  $\bar{y}$ . Thus,  $\underline{u}|_{[0, \tau]}$  is a minimal time control steering  $y^0$  to  $\bar{y}$  and we have  $\|\underline{u}|_{[0, \tau]}\|_{L^\infty} \leq \underline{M} < \underline{M} + 1$ . Consequently,  $\tau$  and  $\underline{u}|_{[0, \tau]}$  are also the minimal time and a time optimal control steering  $y^0$  to  $\bar{y}$  under the control constraint  $\|u\|_{L^\infty} \leq \underline{M} + 1$  (and without state constraint). But due to the saturation property (see (Lee & Markus, 1967)), any time optimal control solution of the above time optimal control problem shall satisfy  $\|u\|_{L^\infty} = \underline{M} + 1$ . This contradicts the fact that  $\underline{u}$  is a time optimal control.  $\square$

### 4.3. Approximation of the minimal time function with control constraints

In order to systematically ensure existence of classical minimal time controls, we add the control constraint  $\|u\|_{L^\infty} \leq M$  for some  $M > 0$  (destined to be large). We define  $T_C^M(y^0, y^1)$  as the minimal time required to steer the control system (2) from  $y^0$  to  $y^1$  under the control constraint  $\|u\|_{L^\infty} \leq M$  and under the state constraint  $C$  (with the agreement that  $T_C^M(y^0, y^1) = +\infty$  when  $y^1$  is not reachable from  $y^0$ ). We have  $T_C(y^0, y^1) = T_C^{+\infty}(y^0, y^1)$  and obviously we have  $T_C(y^0, y^1) \leq T_C^M(y^0, y^1)$  and the function  $M \mapsto T_C^M(y^0, y^1)$  is nonincreasing.

**Proposition 7.**  $\lim_{M \rightarrow +\infty} T_C^M(y^0, y^1) = T_C(y^0, y^1)$ .

**Proof.** We denote, in short,  $T_C = T_C(y^0, y^1)$  and  $T_C^M = T_C^M(y^0, y^1)$ . Let us consider a minimizing sequence  $(T_n)_{n \in \mathbb{N}}$  converging to  $T_C$ , associated with controls  $u_n \in L^\infty((0, T_n), \mathbb{R}^m)$  steering the system (2) to  $y^1$  in time  $T_n > 0$  under the state constraint  $y(t) \in C$ . Set  $M_n = \|u_n\|_{L^\infty}$ . Since  $T_C \leq T_C^{M_n} \leq T_n$ , it follows that  $T_C^{M_n} \rightarrow T_C$  as  $n \rightarrow +\infty$ . Since  $T_C^M \leq T_C^{M_n}$  when  $0 < M_n \leq M$ , the conclusion follows.  $\square$

## 5. Explicit computations in 2D

In this section, we take  $n = 2$  and  $m = 1$  ( $B$  is a vector in  $\mathbb{R}^2$ ). The Brunovsky normal form for the control system (2) is then

$$\dot{z}_1 = z_2, \quad \dot{z}_2 = v, \tag{13}$$

with  $z = (z_1, z_2)^\top = P^{-1}y$  and  $v = Fy + u$ , and with  $F = DA^2, (P^{-1})^\top = (D^\top (DA)^\top)$  and  $D = (0 \ 1)(B \ AB)^{-1}$ . Steering (2) from  $y^0$  to  $y^1$  under the state constraint  $y(t) \in C$  is equivalent to steering (13) from  $z^0 = P^{-1}y^0$  to  $z^1 = P^{-1}y^1$  under the state constraint  $z(t) \in P^{-1}C$ . For  $y^0$  and  $y^1$  two steady-states,  $z^0$  and  $z^1$  are two steady-states as well and thus  $z^i = (z_1^i, 0)^\top$  for  $i \in \{0, 1\}$ . Consequently, without loss of generality, we aim to find the minimal controllability time in order to steer the system (13) from  $z^0 = (z_1^0, 0)^\top$  to  $z^1 = (z_1^1, 0)^\top$  under the state constraint  $z(t) \in C$ . Let us define, for every  $\zeta_1 \in \mathbb{R}$ ,

$$\varphi_+(\zeta_1) = \begin{cases} 0 & \text{if } (\zeta_1, 0)^\top \notin C, \\ \sup \{ \zeta_2 \in \mathbb{R}_+ \mid \forall \zeta \in [0, \zeta_2], \\ (\zeta_1, \zeta)^\top \in C \} & \text{otherwise} \end{cases}$$

and similarly,

$$\varphi_-(\zeta_1) = \begin{cases} 0 & \text{if } (\zeta_1, 0)^\top \notin C, \\ \sup \{ \zeta_2 \in \mathbb{R}_+ \mid \forall \zeta \in [-\zeta_2, 0] \\ (\zeta_1, \zeta)^\top \in C \} & \text{otherwise.} \end{cases}$$

The functions  $\varphi_\pm$  can take the value  $+\infty$ .

**Proposition 8.** Assume that  $C \subset \mathbb{R}^2$  is a closed and simply connected set and  $z^0 = (z_1^0, 0)^\top$  and  $z^1 = (z_1^1, 0)^\top$  are two steady-states in  $C$ , such that the segment  $[z^0, z^1]$  belongs to the interior of  $C$ . Then

$$T_C(z^0, z^1) = \begin{cases} \int_{z_1^1}^{z_1^0} \frac{d\zeta}{\varphi_-(\zeta)} & \text{if } z_1^1 \leq z_1^0, \\ \int_{z_1^0}^{z_1^1} \frac{d\zeta}{\varphi_+(\zeta)} & \text{if } z_1^1 \geq z_1^0. \end{cases}$$

**Proof.** Let us define  $\tilde{C}$  as the closure of

$$\{ (\zeta_1, \zeta_2)^\top \in \mathbb{R}^2 \mid \varphi_+(\zeta_1) > 0, \varphi_-(\zeta_1) > 0, \\ -\varphi_-(\zeta_1) < \zeta_2 < \varphi_+(\zeta_1) \}.$$

Since  $\tilde{C} \subset C$ , we have  $T_{\tilde{C}}(z^0, z^1) \geq T_C(z^0, z^1)$  where  $T_{\tilde{C}}(z^0, z^1)$  is the time required to steer (13) from  $z^0$  to  $z^1$  under the state constraint  $z(t) \in \tilde{C}$ . Moreover, noting that if  $z_2 > 0$  (resp.,  $z_2 < 0$ ) then  $z_1$  is increasing (resp., decreasing), a simple argument shows that any controlled trajectory in  $C$  steering  $z^0 = (z_1^0, 0)^\top$  to  $z^1 = (z_1^1, 0)^\top$  remains in  $\tilde{C}$ . Therefore,  $T_{\tilde{C}}(z^0, z^1) = T_C(z^0, z^1)$ . Let us assume that  $z_1^0 < z_1^1$  (the proof for the other case is similar). Considering the control system  $\dot{z}_1 = z_2$  with  $z_2$  as a control subject to  $z_2 \leq \varphi_+(z_1)$ , we obtain  $T_C(z^0, z^1) \leq \int_{z_1^0}^{z_1^1} \frac{dz_2}{\varphi_+(z_2)}$ .

Let us prove the equality by using Proposition 7. For  $M > 0$ , we define the sets

$$\tilde{C}_+^M = \left\{ \left( \zeta_1^0 + \frac{T^2 M}{2}, T \right) \in \mathbb{R}^2 \mid T \geq 0, \zeta_1^0 \in \mathbb{R} \right. \\ \left. \text{s.t. } \forall t \in [0, T], \left( \zeta_1^0 + \frac{t^2 M}{2}, t \right) \in \tilde{C} \right\},$$

$$\tilde{C}_-^M = \left\{ \left( \zeta_1^1 - \frac{T^2 M}{2}, T \right) \in \mathbb{R}^2 \mid T \geq 0, \zeta_1^1 \in \mathbb{R} \right. \\ \left. \text{s.t. } \forall t \in [0, T], \left( \zeta_1^1 - \frac{t^2 M}{2}, t \right) \in \tilde{C} \right\},$$

$$\tilde{C}^M = \left( \tilde{C}_+^M \cup \tilde{C}_-^M \right) \cap \left( \tilde{C}_-^M \cup \tilde{C}_+^M \right).$$

In particular, we have  $\tilde{C}^M \subset \tilde{C}$  and  $\tilde{C}^M$  contains all trajectories of (13) starting from a steady-state point and reaching a steady-state point under the control constraint  $|v(\cdot)| \leq M$  and under the state constraint  $\tilde{C}$ . Similarly to  $\varphi_\pm$ , we define  $\varphi_\pm^M$  and we check that  $\varphi_\pm^M(\zeta) \leq \varphi_\pm(\zeta)$  and  $\varphi_\pm^M(\zeta) \rightarrow \varphi_\pm(\zeta)$  as  $M \rightarrow +\infty$  for every  $\zeta \in \mathbb{R}$ . Furthermore, the minimal time  $T_{\tilde{C}^M}(z^0, z^1)$  required to steer the system (13) from  $z^0$  to  $z^1$  under the control constraint  $|v(\cdot)| \leq M$  and under the state constraint  $\tilde{C}^M$  is  $\int_{z_1^0}^{z_1^1} \frac{dz_2}{\varphi_+^M(z_2)}$ . Taking the limit  $M \rightarrow +\infty$  gives the result.  $\square$

**Remark 9.** The minimal time control problem for the 2D system (13) under the state constraint  $z_2(t) \in [-\varphi_-(z_1(t)), \varphi_+(z_1(t))]$  and under the control constraint  $|v(\cdot)| \leq M$  can easily be solved when  $\varphi_+$  and  $\varphi_-$  are Lipschitz: given any  $M > 0$  larger than the Lipschitz constants of  $\varphi_+$  and  $\varphi_-$ , the minimal time trajectory coincides with the minimal time trajectory without state constraint intersected with  $\partial C$  (see Fig. 3). In other words: take the optimal solution

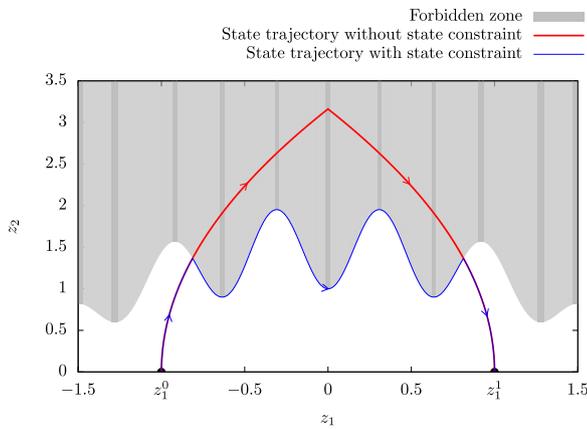

Fig. 3. Relations between the state trajectory with and without the state constraint and under the control constraint  $|v(\cdot)| \leq M$ .

without state constraint, truncate it with the allowed domain, and follow the lines.

The above comment is also valid when considering directly the control system (2) (for  $n = 2$  and  $m = 1$ ). More precisely, for a state constraint of order one, the minimal time trajectory between two steady-states, for the problem under state constraint and under control constraint  $|u(\cdot)| \leq M$  with  $M > 0$  sufficiently large, is exactly the optimal trajectory for the problem without state constraint, and constraint  $M$  on the control, "intersected" with the authorized domain. This fact is however not true when  $n \geq 3$ .

**Example 10.** Take

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}, B = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, y^0 = \begin{pmatrix} 1 \\ 1/2 \end{pmatrix}, y^1 = \begin{pmatrix} 2 \\ 1 \end{pmatrix}$$

and the state constraints  $y_1(\cdot) \geq 0$  and  $y_2(\cdot) \geq 0$  (i.e.,  $C = [0, +\infty)^2$ ). Setting  $z = P^{-1}y$  and  $v = (-1 \ 4)y + u$ , with  $P^{-1} = \begin{pmatrix} -1 & 1 \\ -1 & 2 \end{pmatrix}$ , we obtain the Brunovsky normal form (13) and the aim is to steer  $z^0 = P^{-1}y^0 = (-1/2, 0)^T$  to  $z^1 = P^{-1}y^1 = (-1, 0)^T$  under the state constraints  $z_2 \geq 2z_1$  if  $z_1 \geq 0$  and  $z_2 \geq z_1$  if  $z_1 \leq 0$ . For every  $z_1 \in \mathbb{R}$ , we compute  $\varphi_+(z_1) = 0$  if  $z_1 > 0$  and  $+\infty$  if  $z_1 < 0$ , and  $\varphi_-(z_1) = 0$  if  $z_1 > 0$  and  $-z_1$  if  $z_1 \leq 0$ .

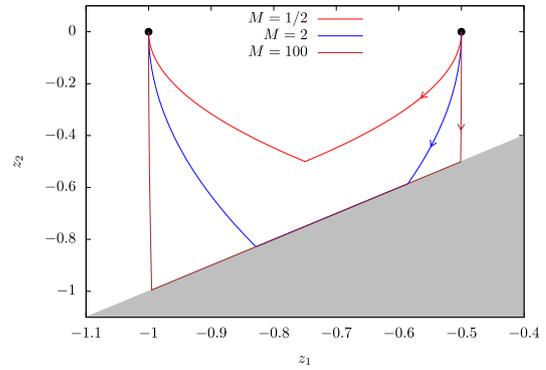

According to Proposition 8, we obtain  $T_C(y^0, y^1) = \int_{-1}^{-1/2} \frac{d\zeta}{\varphi_-(\zeta)} = \ln 2$  and  $T_C(y^1, y^0) = \int_{-1}^{-1/2} \frac{d\zeta}{\varphi_+(\zeta)} = 0$ . On Fig. 4, one can see a sequence of minimal time trajectories under the control constraint  $|v(\cdot)| \leq M$  for  $M \in \{1/2, 2, 100\}$ , steering the system from  $y^0$  to  $y^1$ . In accordance with Proposition 7, the corresponding sequence of minimal times converges to the minimal time given above. Simple computations show that, under the control constraint bound  $M$ , the minimal time is  $\sqrt{2/M}$  when  $M < 9/8$  and  $\sqrt{1 + 2/M} - \sqrt{1 - 1/M} + \ln\left(\frac{\sqrt{1+2/M}-1}{1-\sqrt{1-1/M}}\right)$  when  $M \geq 9/8$  (see also Fig. 5).

Example 10 illustrates Proposition 8. The next example shows that the situation is more intricate when  $C$  is not simply connected.

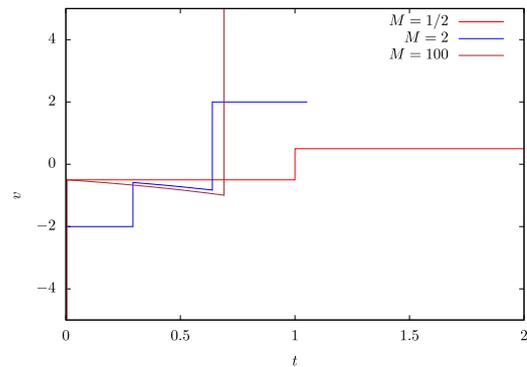

**Example 11.** We consider the set  $C$  drawn and defined by Fig. 6, which is not simply connected.

The objective is to steer the control system (13) from  $z^0 = (-1, 0)^T$  to  $z^1 = (1, 0)^T$  under the state constraint  $C$ . Proposition 8 would give the minimal time  $\int_{-1}^1 \frac{d\zeta_2}{1} = 2$ , but in fact the minimal time is  $\int_{-1}^{-2} \frac{d\zeta}{4} + \int_{-2}^2 \frac{d\zeta}{4} + \int_2^1 \frac{d\zeta}{4} = \frac{3}{2}$  (see Fig. 7 to have an idea of this fact).

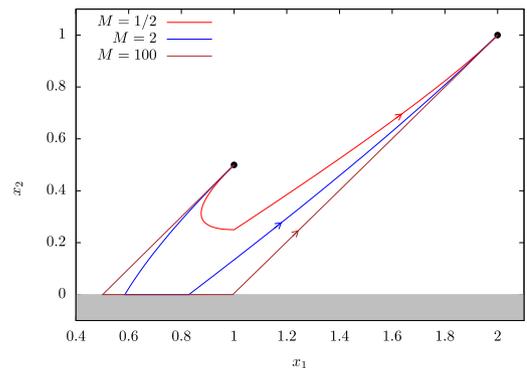

Optimal trajectories under the additional control constraint  $|v(\cdot)| \leq M$  are plotted on Fig. 7. For  $M > 0$  large enough, starting

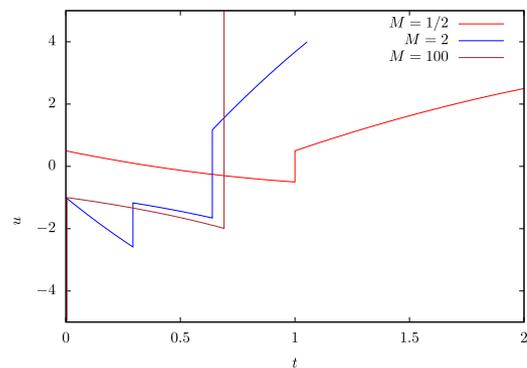

(a) State trajectories in Brunovsky variables

(b) Control in Brunovsky variables

(c) State trajectories in initial variables

(d) Control in initial variables

Fig. 4. Minimal time trajectories steering  $y^0$  to  $y^1$  in Brunovsky variables (top) and in initial variables (bottom) for the state constraint problem, under the additional control constraint  $|v(t)| \leq M$ , for  $M \in \{1/2, 2, 100\}$ .

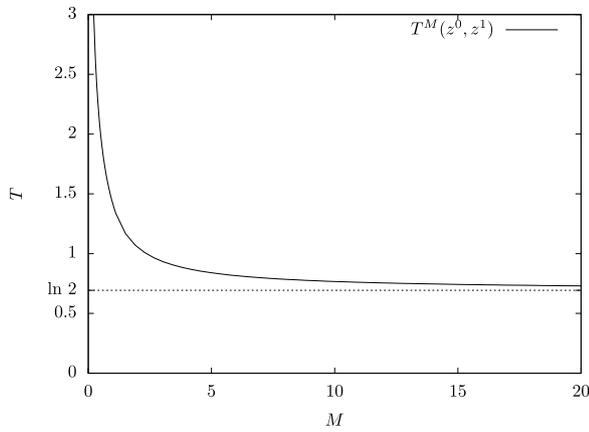

Fig. 5. Convergence of the minimal time control with  $|v(t)| \leq M$  in Brunovsky variables, as  $M \rightarrow \infty$ .

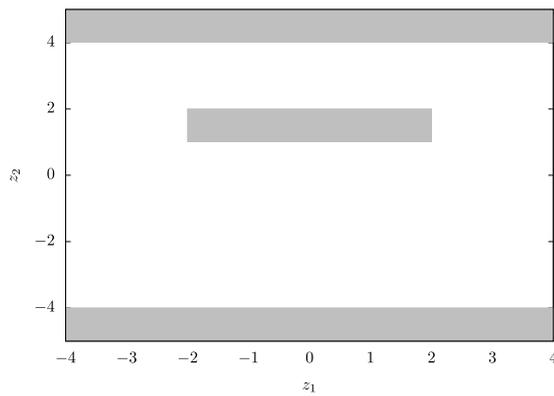

Fig. 6. State constraint set considered in Example 11, the forbidden zones are in gray.

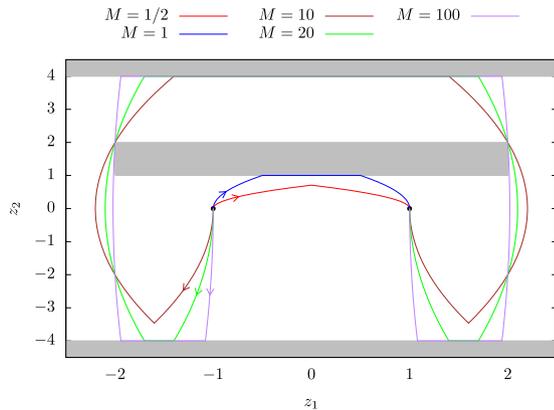

Fig. 7. Minimal time trajectories under the state constraints given in Fig. 6, and under the additional constraint  $|v(\cdot)| \leq M$ , for  $M \in \{\frac{1}{2}, 1, 10, 20, 100\}$ .

from  $z^0 = (-1, 0)^\top$ , the trajectory first goes to the left, then saturates the constraint  $z_2 = -4$ , then goes to the right and grazes the obstacle in the middle, before hitting the constraint  $z_2 = 4$  and following it for a while; and then, symmetrically to the final point.

### 6. Conclusion and further comments

We have shown that steering a finite-dimensional linear autonomous control system satisfying the Kalman condition, under

state constraints but without control constraints, may require a positive minimal time, even for unilateral state constraints. We have proved that the positive minimal time phenomenon occurs for a bounded state constraint set, and more surprisingly, generically occurs for linear control systems as soon as there are more affine state constraints than controls ( $m \leq k$ ), but does not generically occur in the converse situation ( $m > k$ ). We have extended our results to nonlinear control-affine systems, providing evidence that, when  $m = 1$ , the positive minimal time is rather due to the occurrence of singular trajectories, which is a typical nonlinear phenomenon.

Some remarks and open issues are in order.

- We have shown that there does not exist any classical  $L^\infty$  control realizing controllability exactly at the minimal time, but could we expect that there exists a control in the wider space of Radon measures. This is in particular the case for the heat equation with nonnegative Dirichlet controls (cf. Lohéac, Trélat, & Zuazua, 2017).
- A problem related to the above point is the existence a gap between the minimal time obtained for the reduced system and the minimal time for the initial system. The example given in Section 2.6 indicates that such a gap may exist. But this example is very particular since the minimal time for the reduced system is zero. We point out that we did not find examples where a gap exists and the minimal time for the reduced system is positive.
- Explicit minimal times have been given for 2D systems (and lower bounds are given in Lohéac et al. (2017) for the heat equation). Obtaining such expressions, or at least, estimates, is an open problem in larger dimension.
- The two latter items may certainly be addressed within impulsive optimal control theory (see Bressan & Rampazzo, 1988, 1991; Forcadel, Rao, & Zidani, 2013; Müller & Rubanovich, 2003; Silva & Vinter, 1997). An open question is to investigate whether a version of the Pontryagin maximum principle, valid for Radon measures control, would allow one to provide evidence of a positive minimal time, and to study the regularity of the resulting function (see Rao & Kunisch, 2017). It can be noted that, already in the classical context, the study of the minimal time function under state constraints is a difficult issue (see Hartl, Sethi, & Vickson, 1995).
- Accordingly, we have proved that the minimal time function  $T_C^M$  under the additional control constraint  $|u(\cdot)| \leq M$  converges to the minimal time function  $T_C$  as  $M \rightarrow +\infty$ . Obtaining convergence rates is an open question. Another interesting question is to establish as well the convergence of the optimal trajectory, of the optimal control and of the adjoint vector resulting from the Pontryagin maximum principle (the latter convergence being certainly a more challenging issue).
- For unilateral constraints, when there is a positive minimal time  $T_C$ , the optimal structure seems to be a jump at the initial time, followed by a boundary or a singular arc over a time  $T_C$ , and then a jump at the final time. This structure, known in some finite-dimensional problems as *cheap control*, is also reminiscent of the *turnpike phenomenon* in optimal control (see Trélat & Zuazua, 2015). It seems to occur as well for infinite-dimensional systems such as the heat equation (see Lohéac et al., 2017 for the linear case and (Pighin & Zuazua, 2018) for the semilinear case) but the investigation of such problems within the context of impulsive controls remains to be done.

- As we have seen in the proof of [Theorem 1](#), unilateral state constraints finally lead to nonnegative control constraints on a reduced control system. This type of control problem is studied with more details in [Lohéac et al. \(0000\)](#) and in [Lohéac et al. \(2017\)](#) for the heat equation with Dirichlet controls. In particular, in [Lohéac et al. \(0000\)](#), we establish that if the matrix of the reduced system has a real eigenvalue, then there exists a time optimal control in the space of Radon measures and this control is a finite sum of Dirac masses. In addition, if all eigenvalues of this matrix are real, then this time optimal Radon measure control is unique. In this reduced system, some parts of the state have been ignored, but they might be recovered with additional derivatives of Dirac masses located at the initial and final times, as mentioned in the third point of [Section 2.7](#).

**Jérôme Lohéac** was born in 1985. In 2012, he defended his Ph.D. in Applied Mathematics at University of Lorraine, France, under the direction of M. Tucsnak and J.-F. Scheid. Then, he was post-doc at BCAM, Bilbao (Spain), under the supervision of E. Zuazua (ERC project NUMERIWAVES). He gets the position of junior researcher at CNRS, France in 2014 and moved to IRCCyN, Nantes. Since 2017, he is researcher at CRAN, Nancy. His research interests are control theory in finite and infinite dimension, optimal control, and fluid–structure interactions.

**Emmanuel Trélat** was born in 1974. He is currently full professor at University Pierre et Marie Curie (Paris 6) and member of Institut Universitaire de France. He is the director of the Fondation Sciences Mathématiques de Paris. He is editor in chief of the journal ESAIM: Control Calculus of Variations and Optimization, and is associated editor of many other journals. He has been awarded the SIAM Outstanding Paper Prize (2006), Maurice Audin Prize (2010), Felix Klein Prize (European Math. Society, 2012), Blaise Pascal Prize (french Academy of Science, 2014), Big Prize Victor Noury (french Academy of Science, 2016). He is invited speaker at ICM 2018. His research interests range over control theory in finite and infinite dimension, optimal control, stabilization, geometry, numerical analysis.

**Enrique Zuazua** Eibar, Basque Country–Spain, 1961 (<http://www.uam.es/matematicas/ezuazua>) is a Professor of Applied Mathematics at Universidad Autónoma de Madrid (UAM) and a Distinguished Senior Researcher in DeustoTech at the University of Deusto, Bilbao – Basque Country – Spain.

He is also a honorary member of Jakiunde, the Basque Academy of Sciences, Letters and Humanities, a Visiting Professor at Sorbonne Université in Paris and Sichuan University in Chengdu (China), Doctor Honoris Causa from the University of Lorraine, France, member of Academia

Europaea and an Ambassador of the Friedrichs-Alexandre University in Erlangen-Nuremberg, Germany.

From 2008 to 2012, he was the Founding Scientific Director of the BCAM–Basque Center for Applied Mathematics.

He holds a degree in mathematics from the University of the Basque Country, and a dual Ph.D. degree from the same university (1987) and the “Université Pierre et Marie Curie”, Paris (1988). In 1990 he became Professor of Applied Mathematics at the Universidad Complutense de Madrid, to later move to UAM in 2001.

He has been awarded the Euskadi (Basque Country) Prize for Science and Technology 2006 and the National Julio Rey Pastor Prize 2007 in Mathematics and Information and Communication Technology and the Advanced Grants of the European research Council (ERC) NUMERIWAVES in 2010 and DYCON in 2016.

With over 200 articles published, his work has had an important impact (h-index = 33). He has supervised 24 Ph.D. students and over 25 postdoctoral researchers.

His fields of expertise in the area of Applied Mathematics cover topics related with Partial Differential Equations, Systems Control and Numerical Analysis.

In collaboration with Xu Zhang he is the editor-in-chief of the Journal “Mathematical Control and Related Fields” and member of the editorial committee of other Journals and of scientific committees of various centers and agencies.

He develops also an intense dissemination agenda, gathered at: <http://www.enzuazua.net>.
