Numerical approximation for a nonlinear membrane problem

Nabil Kerdid* Hervé Le Dret† ‡ Abdelkader Saïdi§

Abstract

We present a numerical study of large deformations of nonlinearly elastic membranes. We consider the nonlinear membrane model obtained by H. Le Dret and A. Raoult using Γ-convergence, in the case of a Saint Venant-Kirchhoff bulk material. We consider conforming $P_1$ and $Q_1$ finite element approximations of the membrane problem and use a nonlinear conjugate gradient algorithm to minimize the discrete energy. We present numerical tests including membranes subjected to live pressure loads.

Keywords: Nonlinear elasticity, Membranes/thin films, Finite element approximation

1 INTRODUCTION

The purpose of this article is to devise numerical approximations of large deformations of a nonlinearly elastic membrane. The nonlinear membrane model used here was obtained in [13], with refinements in [16]. The relevance of this model stems from the fact that it was derived from three-dimensional nonlinear elasticity by means of a rigorous convergence method. Similar nonlinear membrane models had already been obtained previously by Pipkin, directly in the context of standard two-dimensional membrane theory and using relaxation, see [19].

Our numerical study of the nonlinear membrane model is made possible due to the explicit formula for the nonlinear membrane energy given in [13] in the

case of the Saint Venant-Kirchhoff bulk material. For a general bulk material, an explicit computation of the corresponding nonlinear membrane energy entails the determination of the quasiconvex envelope of a function defined on the space of $3 \times 2$ matrices, a hopeless task as a general rule.

The work of [13] was motivated by [1], the first article to deal with a genuine dimension reduction in nonlinear elasticity via a mathematical convergence result in the case of nonlinearly elastic strings. It was followed in recent years by many, sometimes highly technical developments, including derivations of inextensional bending models and Von Kármán type models, see [7, 8, 9], among others. We are not however aware of the energies found in [13, 16] ever being used in a numerical context, even though there are many numerical works on membranes and thin films, see [2, 10] for numerical studies of Pipkin’s model using a differential equation approach, including the case of a pressurized membrane [22], see also more or less ad hoc models designed for simplicity or efficiency, for instance in [6, 17, 18]. The modeling and numerical simulation of nonlinear membranes is also attracting increasing interest for materials with more sophisticated material response than just nonlinear elasticity, see [23] for finite strain, viscoelastic membranes.

One purpose of the present article is to advocate the use of a rigorously derived membrane energy to perform computations that are grounded on an indisputable three-dimensional model and are still efficient. Naturally, we then have to work with what is given by the asymptotic dimensional reduction procedure, and not with an ad hoc energy. This involves a little bit of mathematics, which needs to be carefully done, see section 3 below.

This article is organized as follows: We first briefly present the results of [13] and [16]. We consider a three-dimensional hyperelastic homogeneous cylinder of thickness $2\varepsilon > 0$ made of a given Saint Venant-Kirchhoff material. The body is subjected to a dead loading body force density and a constant pressure differential on its upper and lower surfaces, and a boundary condition of place on its lateral surface. The three-dimensional nonlinear elasticity equilibrium problem is formulated as a minimization problem for the total energy of the body.

Using $\Gamma$-convergence arguments, H. Le Dret and A. Raoult showed that deformations that almost minimize the three-dimensional total energy converge when the thickness $\varepsilon$ of the body goes to zero towards deformations that minimize a nonlinear membrane energy, see [13]. The convergence takes place in a rescaled weak $W^{1,p}$ sense. The limit problem is two-dimensional, with values in $\mathbb{R}^3$.

The limit two-dimensional nonlinear membrane energy is computed in two steps: First minimize the bulk stored energy function with respect to the third column vector of the deformation gradient—this step produces a function $W_0$ on the space of $3 \times 2$ matrices—then take the quasiconvex envelope of $W_0$. In the special case of a Saint Venant-Kirchhoff material, an explicit formula for this
quasiconvex envelope $QW_0$ is available. This formula is expressed in terms of the right singular values of the membrane deformation. In [16], in addition to the case of curved membranes, the zero-thickness limit of a constant live pressure loading term is also computed.

In section 3, we present a conforming finite element approximation of the membrane problem. We consider $P_1$ and $Q_1$ discretizations of the three Cartesian components of the deformation. In the $P_1$ case, deformations are approximated by piecewise affine, globally continuous functions on a triangulation of the domain. In the $Q1$ case, which is appropriate for rectangular membranes, a rectangular mesh is used with globally continuous approximations that are piecewise of partial degree less or equal to one on the rectangular elements. We prove the weak-$W^{1,4}$ convergence of the approximate solutions toward a solution of the continuous minimization problem.

The choice of available numerical methods to solve our FE problem is rather limited since the problem under study is highly nonlinear and the membrane stored energy function is only of class $C^1$. Consequently, a method relying on second derivatives of the total energy such as the Newton-Raphson method cannot be appropriate. On the contrary, the nonlinear conjugate gradient method with the Polak and Ribière variant seems to be well adapted to our problem. The convergence of the algorithm is guaranteed for a convex functional, which is only the case here when the pressure differential is zero. There is however a slight difficulty in computing the gradient of the stored energy function. We adapted Ball’s results concerning the differentiability of frame-indifferent, isotropic functions on the space of $n \times n$ square matrices, see [4].

In section 4, we present various numerical tests. Both $P_1$ and $Q_1$ elements are alternatively used. The first test is a circular membrane subjected to an upward pressure differential and clamped on its boundary. It should be noted that in our formulation, there as absolutely no need to track the deformed normal vector in order to take into account the live loading pressure differential. This is exemplified by the bubble-like deformation computed in this test which bulges out of the supporting circle. Note again that we have not seen our formulation of the pressure term used in a numerical context.

Next, we perform a few tests taken from [21]: a rectangular airbag inflated by an inner pressure and a square membrane attached by its four corners and subjected to a vertical point force applied at its center. As opposed to [21], our model cannot capture wrinkles in detail, because wrinkles are filtered out in the $\Gamma$-limit process, which in turn leads to a well-posed limit minimization problem. Such is the nature of weak convergence. However, wrinkled regions are captured. They are the membrane areas where the deformation gradient lies a region of $3 \times 2$ space where relaxation occurs, i.e., the quasiconvex envelope is such that $QW_0 < W_0$. This occurs in compression when at least one of the singular values is
less than 1 and the other one is not too large, see [13] for details.

The last two tests are in the context of the modeling of fabrics. The first test is a square piece of fabric attached at its center and subjected to a vertical dead loading body force and the second is a tablecloth with no displacement allowed on the table surface. The obtained deformations develop folds and conical points where the normal vector is ill-defined, but this is of no consequence for our handling of the live pressure term.

Part of the results of this article concerning $P_1$ elements and without pressure differential were announced in [12].

2 THE CONTINUOUS PROBLEM

Let us briefly outline the results of [13] and [16], to which we refer the reader for more details. Let $\omega$ be an open, bounded subset of $\mathbb{R}^2$ with Lipschitz boundary. For all $\varepsilon > 0$, we consider a hyperelastic homogeneous body occupying the reference configuration $\Omega_\varepsilon = \omega \times ]-\varepsilon, \varepsilon[$. We assume that the stored energy function of this body is a function $W: M_3 \to \mathbb{R}$ which is continuous, coercive and satisfies growth conditions for an exponent $p \in [3, +\infty]$, where $M_3$ is the space of real $3 \times 3$ matrices. We furthermore assume that the body is subjected to a dead loading body force density $f_\varepsilon$ and to a constant pressure differential $\varepsilon \Delta p$ on its upper and lower surfaces, which is a live load, that is to say a spatially constant pressure $p_\varepsilon^+$ on the upper surface and another spatially constant pressure $p_\varepsilon^-$ on the lower surface such that $p_\varepsilon^+ - p_\varepsilon^- = \varepsilon \Delta p$. The equilibrium problem for this body may be formulated as a minimization problem for the energy

$$J_\varepsilon(\phi) = \int_{\Omega_\varepsilon} W(\nabla \phi) \, dx - \int_{\Omega_\varepsilon} f_\varepsilon \cdot \phi \, dx - P_\varepsilon(\phi),$$

where

$$P_\varepsilon(\phi) = \int_{\Omega_\varepsilon} \left[ \pi_\varepsilon \det \nabla \phi + \frac{1}{3} \nabla \pi_\varepsilon \cdot (\text{cof} \nabla \phi^T \phi) \right] \, dx,$$

over a set of admissible deformations $\phi$ belonging to an appropriate Sobolev space and satisfying given boundary conditions of place on part of the lateral boundary. Here, $\pi_\varepsilon$ is a $C^1$-function on $\widehat{\Omega_\varepsilon}$ that takes the values $p_\varepsilon^\pm$ on the upper and lower surfaces. The term $P_\varepsilon$ appearing in the energy accounts for the pressure load, see [3]. Note that this term incorporates the fact that a pressure load is a live load that follows the normal vector to the deformed body, without having to keep track of this normal vector. Dead loading tractions on the upper, lower and lateral surfaces can also easily be added as well as boundary conditions of place on part of the boundary.
In [13] and [16], see the latter for the pressure term, Le Dret and Raoult proved that a rescaled version of the above three-dimensional energy $\Gamma$-converges when the thickness $2\varepsilon$ of the membrane goes to zero in the sense of the weak topology of $W^{1,p}(\Omega;\mathbb{R}^3)$, thereby showing that minimizing deformations converge, in an appropriate sense, toward solutions of a two-dimensional minimization problem. The limit, two-dimensional nonlinear membrane problem is described as follows.

Let $\mathbb{M}_{3,2}$ be the space of real $3 \times 2$ matrices. If $z_{\alpha}$, $\alpha = 1, 2$, are two vectors in $\mathbb{R}^3$, we note $(z_1|z_2)$ the matrix of $\mathbb{M}_{3,2}$ whose columns are the vectors $z_{\alpha}$. For all $F = (z_1|z_2) \in \mathbb{M}_{3,2}$ and $z \in \mathbb{R}^3$, we note $(F|z)$ the matrix whose first two columns are $z_{\alpha}$, and third column is $z$ and write $(z|F)$ with a similar convention. We now define a function $W_0: \mathbb{M}_{3,2} \to \mathbb{R}$ by

$$W_0(F) = \inf_{z \in \mathbb{R}^3} W((F|z)).$$

(3)

The function $W_0$ is continuous and coercive. Let $QW_0$ be its quasiconvex envelope, see [5]. We introduce the space of admissible membrane displacements

$$\Phi_M = \{ \psi \in W^{1,p}(\omega;\mathbb{R}^3); \psi(x_1,x_2) = (x_1,x_2,0)^T \text{ on } \partial \omega \},$$

(4)

(this is for the case of a boundary condition of place on the whole lateral surface $\partial \omega \times [-\varepsilon,\varepsilon]$ in the 3D problem, other conditions are enforced accordingly).

The limit nonlinear membrane energy is then defined by

$$J(\psi) = 2 \int_\omega QW_0(\nabla \psi) \, dx_1 dx_2 - \int_\omega f \cdot \psi \, dx_1 dx_2 - \frac{\Delta p}{3} \int_\omega \det(\partial_1 \psi|\partial_2 \psi|\psi) \, dx_1 dx_2,$$

(5)

for all $\psi \in \Phi_M$, where $f$ is a 2D-body force resultant density obtained from $f_\varepsilon$.

The limit minimization problem now reads: Find $\varphi \in \Phi_M$ such that

$$J(\varphi) = \inf_{\psi \in \Phi_M} J(\psi).$$

(6)

The energy functional $J$ is obtained via a $\Gamma$-limit process and existence of a solution to problem (6) is guaranteed under reasonable technical assumptions, see [13] and [16].

In general, it is not possible to compute explicitly the quasiconvex envelope of a given function $W_0$. Hence, generically with respect to the bulk material, it is not possible to perform numerical computations using this model. However, in the special case of a Saint Venant-Kirchhoff material, the quasiconvex envelope $QW_0$ was computed in [13]. Let us recall that the stored energy function of a Saint Venant-Kirchhoff material assumes the form

$$W(F) = \frac{\mu}{4} \text{tr}((F^TF - I_3)^2) + \frac{\lambda}{8} (\text{tr}(F^TF - I_3))^2,$$

5
where $\mu > 0$ and $\lambda \geq 0$ are the Lamé constants of the material (here $F$ is a $3 \times 3$ matrix and $I_n$ is the $n \times n$ identity matrix). The Saint Venant-Kirchhoff energy is the simplest possible frame-indifferent and isotropic nonlinearly elastic stored energy function with a natural state at the identity. It is well suited to the description of the large deflections that are observed in thin membranes.

The intermediate function $W_0$ is given by

$$W_0(F) = \frac{\mu}{4} \text{tr}((F^T F - I_2)^2) + \frac{\lambda \mu}{4(\lambda + 2\mu)} h(F)^2 + \frac{1}{8(\lambda + 2\mu)}\left(([\lambda h(F) - (\lambda + 2\mu)]_+)^2, \right.$$  

with $h(F) = \text{tr}(F^T F - I_2)$ (here $F$ is a $3 \times 2$ matrix, thus $F^T F$ is $2 \times 2$) and $t_+$ denotes the positive part of $t$. Finally, the quasiconvex envelope $QW_0$ is expressed in terms of the right singular values $0 \leq v_1(F) \leq v_2(F)$ of $F$ (i.e. the eigenvalues of $\sqrt{F^T F}$) as

$$QW_0(F) = \Phi(v_1(F), v_2(F)) = 
\frac{E}{8} \left( [v_2(F)^2 - 1]_+ \right)^2 
+ \frac{E}{8(1 - \nu)} \left( [v_1(F)^2 + \nu v_2(F)^2 - (1 + \nu)]_+ \right)^2
+ \frac{E}{8(1 - \nu)(1 - 2\nu)} \left( [v_1(F)^2 + v_2(F)^2 - (1 + \nu)]_+ \right)^2, \tag{7}$$

where $E = \mu(3\lambda + 2\mu) \lambda + \mu$ is the Young modulus and $\nu = \frac{\lambda}{2(\mu + \lambda)}$ the Poisson ratio of the Saint Venant-Kirchhoff material under consideration, see [13] and [15]. It turns out that the function $QW_0$ is convex on $\mathbb{M}_{3,2}$, therefore the quasiconvex envelope of $W_0$ is also its convex envelope in this case.

In the case of the Saint Venant-Kirchhoff material, we thus have a completely explicit expression of the membrane energy that is rigorously derived from three-dimensional nonlinear elasticity by means of a convergence result. The pressure term

$$P(\psi) = \frac{\Delta p}{3} \int_\omega \det(\partial_1 \psi | \partial_2 \psi | \psi) \, dx_1 dx_2$$

also incorporates the fact that we are dealing with a live load that follows the normal to the deformed surface, see [16]. This feature is be very advantageous for numerical simulations since the deformed normal vector does not explicitly enter this formula. There thus is no need to recalculate this vector at each step of the approximation procedure, as opposed to [21] for example.

### 3 THE DISCRETE PROBLEM

#### 3.1 Finite element discretization

We use $P_1$ and $Q_1$ discretizations. Let us describe the $P_1$ case since the $Q_1$ case is entirely similar at this stage. Let $\tau_h$ be a regular affine family of triangulations
covering the domain $\omega$. We discretize the three Cartesian components of the deformation using continuous $P_1$ finite elements. The discrete space of admissible displacements is given by

$$\Phi^h_M = \{ \psi_h \in C^0(\partial \omega; \mathbb{R}^3), \psi_h(x_1, x_2) = (x_1, x_2, 0)^T \text{ on } \partial \omega, \psi_h|_K \in (P_1)^3; \forall K \in \tau_h \}.$$  

We clearly have $\Phi^h_M \subset \Phi_M$ and the approximation is conforming.

We approximate the continuous problem as follows: Find $\phi_h \in \Phi^h_M$ such that

$$J(\phi_h) = \inf_{\psi_h \in \Phi^h_M} J(\psi_h).$$  

This is a convergent approximation scheme in the following sense.

**Proposition 3.1** The weak limit points of the sequence $\phi_h$ in $W^{1,4}$ are minimizers of problem (6).

**Proof.** We first show that the functional $J$ is sequentially weakly lower semicontinuous on $W^{1,4}(\omega; \mathbb{R}^3)$. The first two terms

$$J(\psi) - P(\psi) = 2 \int_\omega QW_0(\nabla \psi) \, dx_1 \, dx_2 - \int_\omega f \cdot \psi \, dx_1 \, dx_2$$

combine to form a convex, strongly continuous functional, hence weakly lower semicontinuous functional on the space $W^{1,4}(\omega; \mathbb{R}^3)$. For the pressure term, we observe that the components of the vector $\partial_1 \psi \wedge \partial_2 \psi$ are null Lagrangians. Since we are in dimension 2, it is well-known that the mapping $\psi \mapsto \partial_1 \psi \wedge \partial_2 \psi$ is sequentially weakly continuous from $W^{1,4}(\omega; \mathbb{R}^3)$ into $L^2(\omega; \mathbb{R}^3)$, see e.g. [3]. Let us consider a weakly convergent sequence $\psi_k \rightharpoonup \psi$ in $W^{1,4}(\omega; \mathbb{R}^3)$. By Rellich’s theorem, we have that $\psi_k \rightarrow \psi$ in $L^2(\omega; \mathbb{R}^3)$ and since $\det((u|v|w)) = (u \wedge v) \cdot w$, it clearly follows that

$$P(\psi_k) = \frac{\Delta p}{3} \int_\omega (\partial_1 \psi_k \wedge \partial_2 \psi_k) \cdot \psi_k \, dx_1 \, dx_2 \rightarrow P(\psi),$$

when $k \rightarrow +\infty$.

Since the functional $J$ is coercive over $\Phi_M$, it follows that the sequence $\phi_h$ is bounded. Let $h'$ be a subsequence such that $\phi_{h'}$ converges weakly in $W^{1,4}(\omega; \mathbb{R}^3)$ to a limit point $\phi$.

Let us now take $\psi \in \Phi_M$. Since the triangulation family is regular, there exists a sequence $\psi_{h'} \in \Phi^h_M$ such that $\psi_{h'} \rightarrow \psi$ strongly in $W^{1,4}(\omega; \mathbb{R}^3)$. Therefore

$$J(\phi) \leq \liminf_{h' \rightarrow 0} J(\phi_{h'}) \leq \lim_{h' \rightarrow 0} J(\psi_{h'}) = J(\psi),$$

hence the result. 

□
Remark 1 By the Rellich-Sobolev embeddings, we also have strong convergence in $C^{0,\alpha}(\bar{\omega};\mathbb{R}^3)$ for all $\alpha < 1/2$. However, even if $\Delta p = 0$ and the functional $J$ is convex, it is not strictly convex. Therefore, we cannot deduce strong $W^{1,4}$ convergence in general, nor any convergence rate.

Note also that the above weak convergence holds true in $W^{1,p}$, not only for the Saint Venant-Kirchhoff material, but for a general material satisfying the hypotheses of [13] with $p > 3$, since quasiconvexity is sufficient to ensure the weak lower semicontinuity of the elastic term in the energy. Besides, the weak lower semicontinuity result can also essentially be viewed as a consequence of the $\Gamma$-convergence result.

\[ \square \]

3.2 The Polak-Ribière nonlinear conjugate gradient algorithm

The boundary value problem underlying problem (6) is highly nonlinear and so is its finite element counterpart. In order to perform numerical computations, we thus need a nonlinear method. The Newton-Raphson method requires the Hessian of $J$ on $\Phi^h_M$, but the function $QW_0$ is not of class $C^2$. Therefore, this method, or any method relying on second derivatives of $J$, is not appropriate. Furthermore, the problem is naturally set as an energy minimization problem. We thus use the nonlinear conjugate gradient method with the Polak and Ribière variant, see [20], which gives the best results. Let us recall that the conjugate gradient algorithm at the $k$th iteration is given by:

\[
\begin{align*}
\psi_{h}^{k+1} &= \psi_{h}^{k} - \rho^k d^k, \\
d^k &= \nabla J(\psi_{h}^{k}) - \beta^{k-1} d^{k-1}, \\
\beta^k &= -\frac{\langle \nabla J(\psi_{h}^{k+1}) - \nabla J(\psi_{h}^{k}), \nabla J(\psi_{h}^{k+1}) \rangle}{\|\nabla J(\psi_{h}^{k})\|^2}, \\
\rho^k &= \frac{d^k \cdot \nabla J(\psi_{h}^{k})}{\|d^k\|^2}.
\end{align*}
\]

Note that the limit membrane energy $J$ is convex for $\Delta p = 0$ in which case the conjugate gradient iterations converge to a global minimum. It is not necessarily convex for $\Delta p \neq 0$, and the nonlinear conjugate gradient may conceivably get trapped at a local minimum.

Even though the method itself is easy to use, the computation of $\nabla J(\psi_{h})$ entails some difficulties. Indeed, since $QW_0$ is a frame-indifferent, isotropic function defined on $\mathbb{M}_{3,2}$ via the right singular values of its argument, viz. formula (7), the computation of $\frac{\partial (QW_0)}{\partial F}$, which is a $3 \times 2$ matrix, requires an adaptation of known results on the differentiation of frame-indifferent, isotropic functions on the space of square matrices $\mathbb{M}_n$, see [4].
3.3 Computation of the gradient of $J$

Let $(\lambda_j)_{j=1,\ldots,N_h}$ be the components of $\psi_h$ in the shape function basis $(\Theta_j)_{j=1,\ldots,N_h}$ of our $P_1$ or $Q_1$ finite element space. We clearly have

$$
\frac{\partial J}{\partial \lambda_j}(\psi_h) = \int_\Omega \frac{\partial}{\partial F}(\nabla \psi_h) : \nabla \Theta_j \, dx_1 \, dx_2 - \int_\Omega f \cdot \Theta_j \, dx_1 \, dx_2
$$

by formula (7).

Lemma 3.2 The matrix $\frac{\partial (QW_0)}{\partial F}(F)$ has the following explicit form:

$$
\frac{\partial (QW_0)}{\partial F}(F) = R \begin{pmatrix} 0 & 0 \\ \partial_1 \Phi(v_1(F),v_2(F)) & \partial_2 \Phi(v_1(F),v_2(F)) \end{pmatrix} S,
$$

where $(v_1(F),v_2(F))$ are the right singular values of the matrix $F$, $R \in O(3)$ and $S \in O(2)$ are orthogonal matrices such that $R^T$ diagonalizes $FF^T \in \mathbb{M}_3$ and $S$ diagonalizes $F^TF \in \mathbb{M}_2$ both with eigenvalues in increasing order, and $\Phi$ is given by formula (7).

Proof. Let us first recall the differentiation result of [4]. Let $Z: \mathbb{M}_n \to \mathbb{R}$ be a function such that $Z(RFS) = Z(F)$ for all $R,S \in O(n)$. It is known that there exists a symmetric function $\Psi: \mathbb{R}^n_+ \to \mathbb{R}$ such that $Z(F) = \Psi(v_1(F),\ldots,v_n(F))$ where $(v_i(F))_{i=1,\ldots,n}$ are the singular values of $F$. In [4], Ball showed that $Z$ is of class $C^1$ if and only if $\Psi$ is of class $C^1$. It is an easy consequence of Ball’s results that in this case,

$$
\frac{\partial Z}{\partial F}(F) = R \text{diag} (\partial_1 \Psi(v_1(F),\ldots,v_n(F)),\ldots,\partial_n \Psi(v_1(F),\ldots,v_n(F))) S,
$$

where $R,S \in O(n)$ are orthogonal matrices occurring in the singular value decomposition of $F = R \text{diag}(v_1(F),\ldots,v_n(F)) S$ with $0 \leq v_1(F) \leq \cdots \leq v_n(F)$. Indeed, for any couple of orthogonal matrices $R$ and $S$, if we let $Z_{R,S}(F) = Z(RFS)$ and differentiate, we obtain that

$$
\frac{\partial Z_{R,S}}{\partial F}(F) = R \frac{\partial Z}{\partial F}(RFS) S = \frac{\partial Z}{\partial F}(F),
$$
hence the result by choosing the right orthogonal matrices.

We now recall a few simple facts about the singular value decomposition. By the polar factorization lemma, any $F \in \mathbb{M}_n$ can be written as $F = QU = VQ$, where $U = \sqrt{F^TF}$ and $V = \sqrt{FF^T}$ are symmetric, positive and $Q \in O(n)$. The symmetric matrices $U$ and $V$ are unique, the orthogonal matrix $Q$ is unique if $\det F \neq 0$, it is nonunique otherwise. Let $S \in O(n)$ be such that $U = S^T \text{diag}(v_i(F))S$. Then we have $F = (QST) \text{diag}(v_i(F))S$, hence a characterization of the orthogonal matrix $S$ to the right of the singular value decomposition of $F$ as a matrix that diagonalizes $F^TF$. Similarly, the orthogonal matrix $R$ to the left of the singular value decomposition of $F$ is a matrix whose transpose diagonalizes $FF^T$, and we have the relation $R = QS^T$. Furthermore, we can always choose these matrices in such a way that the singular values are arranged in increasing order.

Let us go back to the case at hand. Let $F$ be a $3 \times 2$ matrix. It was established in [14] that $QW_0(F) = QW((0|F))$, where $QW$ is the quasiconvex envelope of the Saint Venant-Kirchhoff energy density itself. Since this energy is left and right invariant by $O(3)$, we also have

$$QW_0(F) = QW((0|F)), \quad (13)$$

Therefore, it follows that the column vectors satisfy

$$\left[ \frac{\partial (QW_0)}{\partial F}(F) \right]_\alpha = \left[ \frac{\partial (QW)}{\partial G}((0|F)) \right]_{(1+\alpha)}, \quad (14)$$

for $\alpha = 1, 2$.

By [14], we have an explicit representation of the quasiconvex envelope of the Saint Venant-Kirchhoff density of the form $QW(z|F) = \Psi(v(z|F))$ with $\Psi : \mathbb{R}^3_+ \to \mathbb{R}$. Now, by the general result of [4], it follows that

$$\frac{\partial (QW)}{\partial G}((0|F)) = R \text{diag}(\partial_1 \Psi(0, v_1(F), v_2(F)), \ldots, \partial_3 \Psi(0, v_1(F), v_2(F))) \bar{S}, \quad (15)$$

where $R^T, \bar{S} \in O(3)$ respectively diagonalize $(0|F)(0|F)^T$ and $(0|F)^T(0|F)$, with the requisite order for the singular values. Now we clearly have

$$(0|F)(0|F)^T = FF^T \quad \text{and} \quad (0|F)^T(0|F) = \begin{pmatrix} 0 & 0 \\ 0 & FF^T \end{pmatrix}. \quad (16)$$

Therefore, if $S \in O(2)$ diagonalizes $F^TF$ with the eigenvalues in increasing order, it follows that

$$\bar{S} = \begin{pmatrix} 1 | 0 \\ 0 | S \end{pmatrix}, \quad (17)$$

since 0 is an eigenvalue of the $3 \times 3$ matrix $(0|F)^T(0|F)$.
Now, we just have to identify the last two column vectors in formula (15). This is easy since
\[
\frac{\partial (QW)}{\partial G} = R \begin{pmatrix}
\partial_1 \Psi & 0 & 0 \\
0 & \partial_2 \Psi & 0 \\
0 & 0 & \partial_3 \Psi
\end{pmatrix}
\begin{pmatrix}
1 & 0 \\
0 & S
\end{pmatrix}
\begin{pmatrix}
0 \\
0 \\
S
\end{pmatrix}
= R \begin{pmatrix}
\partial_1 \Psi \\
0 \\
0
\end{pmatrix}
\begin{pmatrix}
0 \\
\partial_2 \Psi \\
0
\end{pmatrix}
S
= R \begin{pmatrix}
\partial_1 \Psi \\
0 \\
0
\end{pmatrix}
\begin{pmatrix}
0 \\
\partial_2 \Psi \\
0
\end{pmatrix}
S
\]
The conclusion follows from the fact that \(\Psi(0, v_1, v_2) = \Phi(v_1, v_2)\) for all \(0 \leq v_1 \leq v_2\), see [14]. □

**Remark 2** The expressions of \(\partial_1 \Phi(v_1, v_2)\) and \(\partial_2 \Phi(v_1, v_2)\) are given by
\[
\partial_1 \Phi(v_1, v_2) = \frac{E}{2(1 - v^2)} v_1 [v_1^2 + vv_2 - (1 + v)] + \frac{Ev}{2(1 - v^2)(1 - 2v)} v_1 [v(v_1^2 + v_2^2) - (1 + v)]
\]
and
\[
\partial_2 \Phi(v_1, v_2) = \frac{E}{2} v_2 [v_2^2 - 1] + \frac{Ev}{2(1 - v^2)} v_2 [v_1^2 + vv_2 - (1 + v)] + \frac{Ev}{2(1 - v^2)(1 - 2v)} v_2 [v(v_1^2 + v_2^2) - (1 + v)]
\]
for all \(0 \leq v_1 \leq v_2\), in view of formula (7). Consequently, to compute the part of the gradient pertaining to \(QW_0\), we only need to compute the two singular values, which entails solving a second degree equation, and a couple of corresponding orthogonal matrices. □

## 4 NUMERICAL TESTS

Note that in the \(P_1\) case, deformation gradients are constant element-wise. Hence the contributions of \(QW_0\) to the energy and its gradient are computed exactly.
However, both dead loading and pressure terms require numerical integration in the $P_1$ as well as $Q_1$ cases. In particular, in the $Q_1$ case, the singular values and orthogonal matrices must be evaluated at Gauss points in each element.

In order to understand the limit model (5) in terms of actual membrane parameters, it should be emphasized that (5) is a rescaled, zero-thickness limit model. In particular, it does not involve the actual nonzero thickness of a given membrane of interest. For instance, the pressure differential $\Delta p$ stands for the limit of $\varepsilon^{-1}\Delta p_\varepsilon$ when $\varepsilon$ goes to zero, where $\Delta p_\varepsilon$ is the actual pressure differential and $\varepsilon$ the half-thickness of the membrane. Likewise, body force resultants are rescaled limits.

Now there are infinitely many different ways of embedding an actual nonzero thickness membrane into a family of membranes with vanishing thickness. We can however agree that such a sequence should be made of the same bulk material, hence have material coefficients that are independent of $\varepsilon$, as we have done in the asymptotic analysis. In this context, the computed results for a limit pressure differential $\Delta p$ of 1.0e+9 as in the first test below, correspond to an actual pressure differential of 50 kPa for a 0.1 mm thick membrane, and so forth. We will only give the rescaled values below, unless otherwise specified.

Let us first present $P_1$ tests. The first test (Figure 1) is a circular membrane subjected to an upward pressure differential and clamped on its boundary. A bubble-like deformation is thus created and it is apparent that the live loading character of the pressure is well taken into account, without having to explicitly track the deformed normal vectors.
Figure 1. Circular membrane with Young modulus $E = 2.7\times10^2$ MPa and Poisson ratio $\nu = 0.4$, corresponding to an elastomer, (rescaled) pressure differential $\Delta p = 1.0$ GPa, zero dead loading body force, 3,243 degrees of freedom.

The convergence of the algorithm is as follows

![Graph showing convergence](image)

Figure 2. Gradient norm/initial gradient norm ratio plotted against iteration number.

Our second $P_1$ test is an airbag: a pillow-like structure subjected to an outward pressure differential that inflates it. To compute it, we use two equal square reference domains corresponding to the upper and lower parts of the airbag, with the condition that horizontal displacements agree and vertical displacements vanish on their common boundary.

![Airbag diagram](image)

Figure 3. $P_1$ airbag, same mechanical data except pressure differential $\Delta p = 1.0\times10^7$, 5,046 degrees of freedom.
It is instructive to compare this test with the corresponding one in [21]. Because of the relaxed nature of the membrane energy we use, there is no need for a special treatment of the areas located near the middle of the airbag sides, where wrinkling occurs. Such wrinkling is smoothed out by the Γ-limit process, as a result of weak convergence. On the other hand, we do not capture wrinkle details. However, our model can predict wrinkled areas which correspond to areas where the deformation gradient lies in the subset of $M_{3,2}$ in which the energy is relaxed. See [13] for a description of this subset in terms of the singular values of the deformation gradient.

Let us now show the results of a few $Q_1$ tests. First is the same airbag as before.
We next compute again the same airbag, with an added point force $f_1 = f_2 = 0$ and $f_3 = -1.0e+9$, slightly off-center on the top surface.

![Figure 6. $Q_1$ airbag with point force.](image)

Back to $P_1$-tests, a square membrane attached by its four corners and subjected to a vertical point force applied at the center.

![Figure 7. Square membrane, with $E = 2.1e+8$, $\nu = 0.25$ and central point force $f_1 = f_2 = 0$ and $f_3 = -1.0e+10$.](image)

Our next tests are in the context of the modeling of fabrics. We take values for the Young modulus $E = 2,500$ Pa and Poisson ratio $\nu = 0.01$ that are characteristic of cotton fabric, see [11]. These values are rescaled with respect to the thickness since the bulk Young modulus of cotton is of the order of 8 GPa.
In Figure 6, we consider a square piece of fabric attached at its center and subjected to a vertical dead loading body force \( f_3 = -1,000 \), slightly counterbalanced by an upward pressure differential \( \Delta p = 100 \). The lateral sides are hanging free.

![Figure 8. Q1 square piece of fabric.](image)

Our last test is a tablecloth. The material constants and applied forces are the same as above, and the displacement is set to zero on the center square that represents the table, \( i.e., \) the fabric is not allowed to slide across the table like an actual tablecloth.
